No increase in the incidence of cesarean delivery was found in the early epidural group nor was the first stage of labor prolonged. Thus if a parturient chooses neuraxial analgesia, there is no point during the first stage of labor that is "too early" to initiate epidural analgesia. Current ASA guidelines note that maternal request for labor pain relief is sufficient justification for epidural initiation and the timing should not depend on an arbitrary cervical dilation.[92]

Epidural Analgesia

Lumbar epidural analgesia offers a safe and effective method of pain relief during labor and is the mainstay of labor analgesia. Epidural analgesia is most commonly initiated after placement of a catheter into the epidural space between L2-3 and L4-5 (see Chapter 45). The analgesia technique is versatile and the block may be made denser and prolonged if operative delivery is required. Typically, a combination of low-dose local anesthetic and opioid are administered to provide continuous sensory block during labor. Benefits of epidural analgesia include decreased maternal catecholamines, effective pain relief, increased patient satisfaction, and the ability to quickly achieve surgical anesthesia for an emergency cesarean delivery.

Prevention of accidental intravascular or intrathecal local anesthetic administration is paramount in the safety of epidural techniques. Initial dosing of local anesthetic through the needle within the epidural space is not recommended because of potential unintended intravascular or intrathecal placement that would result in local anesthetic systemic toxicity or total spinal. Further, most anesthesia providers "test dose" the epidural catheter after placement to assess for intravascular or intrathecal placement.[120] A test dose may consist of a small dose of local anesthetic that would induce an altered sensorium (dizziness, buzzing in the ears, or numbness in the lips) if injected intravascularly but would not cause harm. Likewise, if this small dose were injected into the intrathecal space, it would cause numbness and motor block in the lower extremities but not a high spinal block. Some clinicians favor inclusion of a small dose of epinephrine in the test dose so that if the placement were intravascular, a slight tachycardic and/or hypertensive response would ensue. Overall, even with test dosing, unidentified intravascular or intrathecal catheter placement is possible. This risk can be mitigated by dosing slowly, aspirating the catheter intermittently throughout the injection process, watching for CSF or blood return in the aspirated catheter, and vigilance for rapid and unexpected changes in vital signs, central nervous system (CNS) symptoms, or motor block throughout the dosing process.

Spinal Analgesia

Intrathecal analgesia for labor can be administered as a single dose or as a continuous infusion. A single injection of opioid combined with a small dose of local anesthetic in the subarachnoid space is quick to perform, provides rapid analgesia, and dissipates when no longer needed. A single spinal injection for labor analgesia can be utilized in a parturient who is unable to hold still to facilitate placement of an epidural but is usually reserved for when the duration of labor can be reasonably estimated, such as in multiparous parturients with advanced dilation or in the second stage of labor. Continuous spinal analgesia with a spinal catheter can be considered in the case of accidental dural puncture or in the high-risk parturient. The high incidence of postdural puncture headache (PDPH) precludes the elective placement of spinal catheters through epidural needles in most patients. A catheter-over-needle system provides the option for a 23-gauge intrathecal catheter placed over a 27-gauge pencil-point spinal needle. Although theoretically this should decrease the rate of PDPH, a recent series of five cases reported two cases of PDPH.[121] When utilized, continuous spinal analgesia provides excellent analgesia and can be quickly converted to surgical anesthesia if necessary.

Combined Spinal-Epidural Analgesia

The CSE has become increasingly popular in obstetric anesthesia practice. It provides effective, rapid onset of analgesia with minimal motor blockade. It is most commonly placed utilizing the "needle-through-needle" technique, which involves identification of the epidural space through a loss-of-resistance technique followed by insertion of a long, pencil-point spinal needle (25-27 gauge) into the intrathecal space. After free-flow of CSF is confirmed, an opioid, local anesthetic, or both, is injected. The spinal needle is removed and a catheter is threaded into the epidural space. A large systematic review of 27 trials involving 3275 women found CSE had a faster onset of analgesia and was less likely to need additional epidural boluses. There was no difference between CSE and traditional epidural in terms of incidence of PDPH or rate of cesarean delivery.[122] In one large retrospective review, the incidences of overall failure, inadequate analgesia, and catheter placement were lower in parturients receiving CSE compared to epidural.[123] Disadvantages of CSE include the inability to assess the effectiveness of the epidural catheter until the spinal medication has subsided; however, one study not only found that CSE had lower epidural catheter failures (6.6% vs. 1.6%; $P = .001$) but more failed catheters with CSE (48.4%) than with an epidural (30.6%) were recognized within 30 minutes of placement ($P = .009$).[124]

Dural Puncture Epidural

An emerging technique in labor analgesia is the DPE. After the epidural space is located with the epidural needle, a pencil-point spinal needle is inserted utilizing the "needle-through-needle" technique and the dura is punctured. A 25- or 26-gauge spinal needle is usually used because a DPE placed by a 27-gauge needle was shown to offer no benefit in a single study.[125] No medication is directly introduced into the intrathecal space but the dural puncture may facilitate the intrathecal migration of medication administered into the epidural space. DPE has been associated with a decreased median time to adequate analgesia after block placement.[126] One study found improved block quality (measured by the number of physician administered *top-up* boluses) and a lesser incidence of asymmetric block in the DPE compared to the epidural group,[127] while another study did not observe this difference.[126] More studies are needed to fully understand the role of the DPE in the neuraxial labor analgesia armamentarium.

Neuraxial Analgesic Medications

Any preservative-free local anesthetic can be used in an epidural catheter. A perfect labor analgesic recipe provides excellent analgesia without motor blockade or other maternal or fetal effects. Low concentrations of local anesthetics (alone or in combination with opioids) are used to maximize sensory blockade and minimize motor blockade and maternal hypotension from sympathetic blockade. Most commonly, bupivacaine (0.0625%-0.125%) and ropivacaine (0.0625%-0.2%) are used because the ratio of sensory to motor blockade is greater than that for lidocaine or 2-chloroprocaine. Ropivacaine and levobupivacaine were synthesized to reduce cardiotoxicity that occurs with inadvertent intravascular bolus doses of bupivacaine. However, with the dilute concentrations of local anesthetic currently used for labor analgesia, cardiotoxicity is uncommon.

The addition of fentanyl to bupivacaine has been shown to reduce local anesthetic requirements while still providing similar pain relief.[128,129] Therefore lipid-soluble opioids, fentanyl 1 to 3 μg/mL, or sufentanil 0.1 to 0.5 μg/mL, are typically added to local anesthetic labor epidural mixtures to reduce total local anesthetic administration and thereby reduce motor blockade while preserving analgesia and enhancing maternal satisfaction.[130] Of note, opioid-only epidural regimens do not provide adequate analgesia without unacceptable side effects. The most troublesome complication that limits the dose of epidural fentanyl and sufentanil is pruritus.

The search for the perfect labor epidural drug combination has led to the use of other adjuvant drugs that can reduce the dose of required local anesthetic. Most of these drugs act through activation of adrenergic receptors. Epinephrine is a nonselective adrenergic agonist activating α_1-, α_2-, β_1-, and β_2-adrenergic receptors. Activation of α_1-receptors in the epidural vasculature causes vasoconstriction that delays the vascular uptake of local anesthetic and opioid.[131] Additional analgesia is likely provided by epinephrine through activation of α_2-adrenergic receptors.[132] The dose of epidural epinephrine in labor epidural mixtures is typically dilute (1:400,000-1:800,000) secondary to concerns for uterine artery vasoconstriction by the systemic effects of higher doses. Intrathecal or epidural neostigmine produces analgesia by increasing acetylcholine stimulation of spinal muscarinic and nicotinic receptors.[133-135] Intrathecal neostigmine, however, caused an unacceptable incidence of nausea and vomiting and continued clinical development was abandoned.[133] However, epidural neostigmine has been shown to reduce local anesthetic requirements without nausea and vomiting. A randomized controlled trial compared bupivacaine use in laboring patients when neostigmine versus fentanyl was added and found no difference in bupivacaine requirements.[136]

Clonidine is a relatively selective α_2-adrenergic antagonist that when added to dilute local anesthetic solution provides adjuvant analgesia.[137,138] Although clearly effective for labor analgesia, within the United States epidural clonidine carries a US Food and Drug Administration (FDA) warning that states it is "not recommended for obstetrical, postpartum, or perioperative pain management as the risk of hemodynamic instability (e.g., hypotension, bradycardia) may be unacceptable in this population." Monitoring recommendations related to this statement declare that in "a rare obstetrical, postpartum, or perioperative patient, potential benefits may outweigh possible risks." Dexmedetomidine is a highly selective α_2-adrenergic receptor agonist that is not approved for neuraxial use in the United States.[139] However, when used in combination with epidural bupivacaine or ropivacaine it has been found to be an efficacious adjunct for labor analgesia.[140,141]

Administration Techniques

Epidural analgesia can be administered by continuous infusion, patient-controlled epidural analgesia (PCEA), or programmed intermittent epidural bolus (PIEB). The continuous infusion is commonly utilized because it allows the maintenance of a steady anesthesia level without frequent, time-consuming manual boluses by the anesthesia provider. PCEA allows the patient to self-deliver a dose through the epidural catheter with the use of a pump that limits the maximum drug dose per hour to prevent toxicity. PCEA can be used alone or in combination with a continuous infusion or PIEB. PCEA results in reduced local anesthetic use and decreased motor blockade.[142] PIEB utilizes a pump that gives automated boluses at a fast rate at set intervals instead of a slow continuous infusion. Theoretically, the PIEB function allows for greater, more uniform spread of the epidural infusion thus reducing unilateral blocks, areas of block sparing, and total amounts of local anesthetic required for analgesia. Early studies indicate that this pump function may, in fact, offer such benefits.[143-145]

Contraindications of Neuraxial Anesthesia

Contraindications to the placement of a neuraxial procedure include patient refusal, coagulopathy, infection at the site of needle insertion, uncorrected hypovolemic shock, increased intracranial pressure from mass effect, and inadequate resources or expertise. Relative contraindications may include systemic infection, preexisting neurologic disease, severe cardiac valvular stenosis, and pharmacologic anticoagulation. The decision to place neuraxial anesthesia should be individualized for the patient and the risks and benefits should be considered.

OTHER REGIONAL NERVE BLOCKS

Local anesthetic nerve blocks have been used for many years to relieve labor pain, mostly by obstetricians.[146] For a paracervical block, local anesthetic is injected lateral to the cervix at 4 o'clock and 10 o'clock, taking care to avoid vascular structures. It controls pain of the first stage of labor only and is more effective than placebo or intramuscular meperidine.[147] No difference was found in pain relief comparing paracervical block to PCA with intravenous fentanyl.[148] Paracervical block can be complicated by injection of local anesthetic into the presenting fetal head, which can have devastating consequences. More commonly, side effects of transient fetal bradycardia and maternal local anesthetic toxicity have been reported.[149-151] Therefore for the delivery of a viable fetus, obstetricians in the United States avoid this procedure. The technique of paracervical block is still used in intrauterine fetal demise labor analgesia, dilation and curettage, and dilation and evacuation procedures. It has become safer with more superficial injection ensured by a needle guide and more dilute solutions of local anesthetic.

The pudendal nerve is derived from sacral nerve roots (S2-S4) and can be blocked with local anesthetic using a transvaginal or transperitoneal approach to treat pain during the second stage of labor and for episiotomy repair. Although a pudendal nerve block provides some relief during second stage, it is not as effective as a subarachnoid block with fentanyl and bupivacaine.[152] A pudendal block can impede the urge to push during the second stage of labor.[153] Other complications include a high rate of block failure; systemic local anesthetic toxicity; ischiorectal or vaginal hematoma; and, rarely, fetal injection of local anesthetic.

Anesthesia Considerations for Operative Delivery

Low-dose epidural analgesia can be inadequate for assisted vaginal delivery with forceps or vacuum. In this setting, a higher concentration local anesthetic can be administered through an indwelling epidural catheter. Supplementation of an indwelling epidural catheter with 5 to 10 mL of 1% to 2% lidocaine or 2% to 3% 2-chloroprocaine is usually adequate, depending on whether vacuum or forceps are being used. Pudendal nerve block also can be considered for operative delivery. Consideration could be given to a CSE approach instead of a single injection "second stage spinal" in the event that the operative vaginal delivery fails and cesarean delivery is subsequently required.

Anesthesia for Cesarean Delivery

MATERNAL RISKS AND CONSIDERATIONS

Cesarean delivery rates in the United States increased by 50% between 1998 and 2016, rising from 22% to 32% of all births.[154,155] Common indications for cesarean delivery include fetal malpresentation, nonreassuring fetal status, labor dystocia, and prior cesarean delivery. Although maternal mortality substantially decreased during the first half of the twentieth century, the maternal mortality ratio has not declined in over 25 years and appears to have recently been increasing in the United States.[156] Of interest, the incidence of maternal mortality is 10 times higher in women who underwent cesarean delivery versus vaginal delivery, based on a retrospective study of 1.5 million deliveries between 2000 and 2006.[157]

Pregnant women who undergo general anesthesia for cesarean delivery are at increased risk of pulmonary aspiration of gastric contents, failed intubation of the trachea, or inadequate postoperative ventilation compared with those under neuraxial blockade, particularly in emergent situations. However, it appears that the risks associated with general anesthesia have decreased significantly over time to the point where it is difficult to say that avoiding general anesthesia prevents maternal mortality. Data in the United States from 1979 to 1990 noted a risk ratio of 16.7 for mortality with general anesthesia for cesarean delivery compared with neuraxial blockade,[158] whereas between 1997 to 2002, the risk ratio was not significantly greater with general versus neuraxial anesthesia (RR 1.7; CI, 0.6-4.6, $P = .2$).[159] This reduction in the risk ratio may be because of advanced airway techniques (e.g., supraglottic airways and video laryngoscopy) and safer airway practices (e.g., difficult airway algorithms).

Use of neuraxial anesthesia for cesarean delivery minimizes exposure of the neonate to maternal anesthetic medications, avoids airway manipulation, improves postoperative pain, and allows the mother to see the child almost immediately after birth. All pregnant women should undergo a preoperative evaluation, regardless of planned delivery mode or type of anesthetic technique, with appropriate risk and benefit counseling. The current status of the fetus and obstetric management plan also should be taken into consideration when formulating the anesthetic plan. In addition, appropriate equipment and medications should always remain readily available to safely provide general anesthesia for an emergent or unanticipated situation.

Although the rates of significant maternal aspiration of gastric contents with induction of general anesthesia are difficult to determine, the mortality from such an event is estimated at 5% to 15% based on retrospective data.[160,161] ASA guidelines recommend aspiration prophylaxis with the administration of nonparticulate antacids, H_2 receptor antagonists, and/or metoclopramide before obstetric surgical procedures.[92] The decision to use general anesthesia or neuraxial block for cesarean delivery is determined by a variety of factors that include the fetal condition and urgency of delivery, maternal comorbidities, presence of a previously placed epidural for labor analgesia, surgical considerations, and maternal wishes. At present, most cesarean deliveries in developed countries are performed with neuraxial techniques.

SPINAL ANESTHESIA

If an epidural catheter is not already placed, spinal anesthesia is typically used for nonemergent cesarean deliveries. Compared with an epidural, a single injection spinal is often faster and technically easier to perform, allows adequate operating conditions in a shorter time, provides a denser block, is more cost effective, and is less likely to fail (failure rate <1%).[162,163] Spinal anesthesia is most often administered through a small (24 gauge or smaller), pencil-point needle. On occasion, a continuous spinal catheter may be used for anesthesia for cesarean delivery. As previously discussed, a spinal catheter may be placed in the case of an inadvertent dural puncture but can be placed intentionally for cesarean delivery in high-risk obstetric patients.

The chance of significant maternal hypotension is greater with spinal anesthesia than with epidural anesthesia. Left uterine displacement with appropriate administration of fluids and use of vasopressor medications can minimize the associated hypotension. Intravenous administration of crystalloid or colloid can reduce the degree of hypotension after spinal anesthesia for cesarean delivery.[164] A Cochrane review assessed 11 trials with 698 women comparing colloid versus crystalloid and found significantly fewer women became hypotensive after colloids (RR 0.68; 95% CI, 0.52-0.89).[165] However, concern exists regarding the safety of synthetic colloids as part of intraoperative and critical care resuscitation. Of note, fluid co-loading is thought to have limited efficacy in consistently preventing postspinal hypotension and is typically utilized in combination with a vasopressor.

Historically, ephedrine was considered the vasopressor of choice to manage hypotension caused by neuraxial anesthesia in pregnancy; however, prophylactic or therapeutic phenylephrine in boluses or as an infusion is not only effective in reducing hypotension but also has less transfer to the fetus and results in less fetal acidosis than ephedrine.[62,90,166] Phenylephrine is now considered the vasopressor of choice for the treatment of spinal hypotension, and there is accumulating evidence that administration by prophylactic infusion is most effective in preventing hypotension. A systematic review found prophylactic phenylephrine infusions compared to placebo significantly reduced the risk of hypotension (RR 0.36; 95% CI, 0.18-0.73) and nausea and vomiting (RR 0.39; 95% CI, 0.17-0.91).[167] Phenylephrine is an α-adrenergic receptor agonist and is often associated with reflexive slowing of maternal heart rate and a decrease in cardiac output. There is increasing interest in norepinephrine as an alternative vasopressor for treating spinal hypotension. Compared to phenylephrine, norepinephrine had similar efficacy for maintaining arterial blood pressure during spinal anesthesia for cesarean delivery and was associated with a greater heart rate and cardiac output.[168] Further work needs to be done to assess the safety and efficacy of norepinephrine as the vasopressor of choice to prevent and treat postspinal hypotension.

Although various local anesthetics can be used for spinal blockade, hyperbaric bupivacaine 10 to 12 mg is frequently used to achieve an adequate (T4) level block. Neither patient height nor weight affect block extension,[169] although dosing may require adjustment at extremes of the height spectrum. Lipid soluble opioids (such as fentanyl or sufentanil) may be added to enhance neuraxial blockade by reducing local anesthetic dose and decreasing stimulation from surgical traction of the viscera. Epinephrine (0.1-0.2 mg), may be added to improve the quality and duration of the block.[170] Clonidine can also prolong the duration of the block and improve intraoperative analgesia but can increase sedation and is considered off-label for this use.[171] Preservative-free morphine 0.1 to 0.2 mg or hydromorphone 0.75 mg is frequently administered with the spinal to reduce postoperative pain for 18 to 24 hours after the anesthetic has dissipated.[172,173]

EPIDURAL ANESTHESIA

If an epidural catheter has already been inserted for labor analgesia, it provides an excellent method to provide surgical anesthesia for cesarean delivery. A catheter-based technique allows for the ability to titrate the local anesthetic to the proper block height and provide additional local anesthetic administration during the case. For patients who do not already have a catheter in place, this technique may be chosen if the procedure is anticipated to take additional time, or if maternal comorbidities would favor a more gradual, controlled onset of epidural anesthesia. Achieving surgical block conditions takes longer with an epidural than spinal technique but can be rapid enough for use in many urgent situations if already in place and used for maternal analgesia.

Although use of a rapid-onset local anesthetic such as 3% 2-chloroprocaine to attain a T4 level in a newly placed catheter may take 10 minutes,[174] extension of a T10 *analgesic* level to a *surgical anesthetic* T4 level can be obtained in approximately 5 minutes using 3% 2-chloroprocaine or alkalinized 2% lidocaine.[175] Bupivacaine 0.5% may be used if rapid onset is not needed, but is often avoided because of the increased risk of local anesthetic systemic toxicity. Typical epidural local anesthetic volumes required for cesarean delivery range between 10 and 20 mL, depending on whether the epidural is already in use. The administration of epidural local anesthetic should occur in divided doses to ensure that the catheter has not migrated into the intravascular or intrathecal space. Block quality can be improved with addition of epinephrine 1:200,000, fentanyl 50 to 100 μg, or sufentanil 10 to 20 μg. Epidural clonidine 50 to 100 μg can be useful in patients with preexisting chronic pain or severe hypertension if the benefit is judged to outweigh the risk for hypotension, bradycardia, and sedation. Epidural morphine 2 to 5 mg is frequently administered to improve postoperative pain.[176]

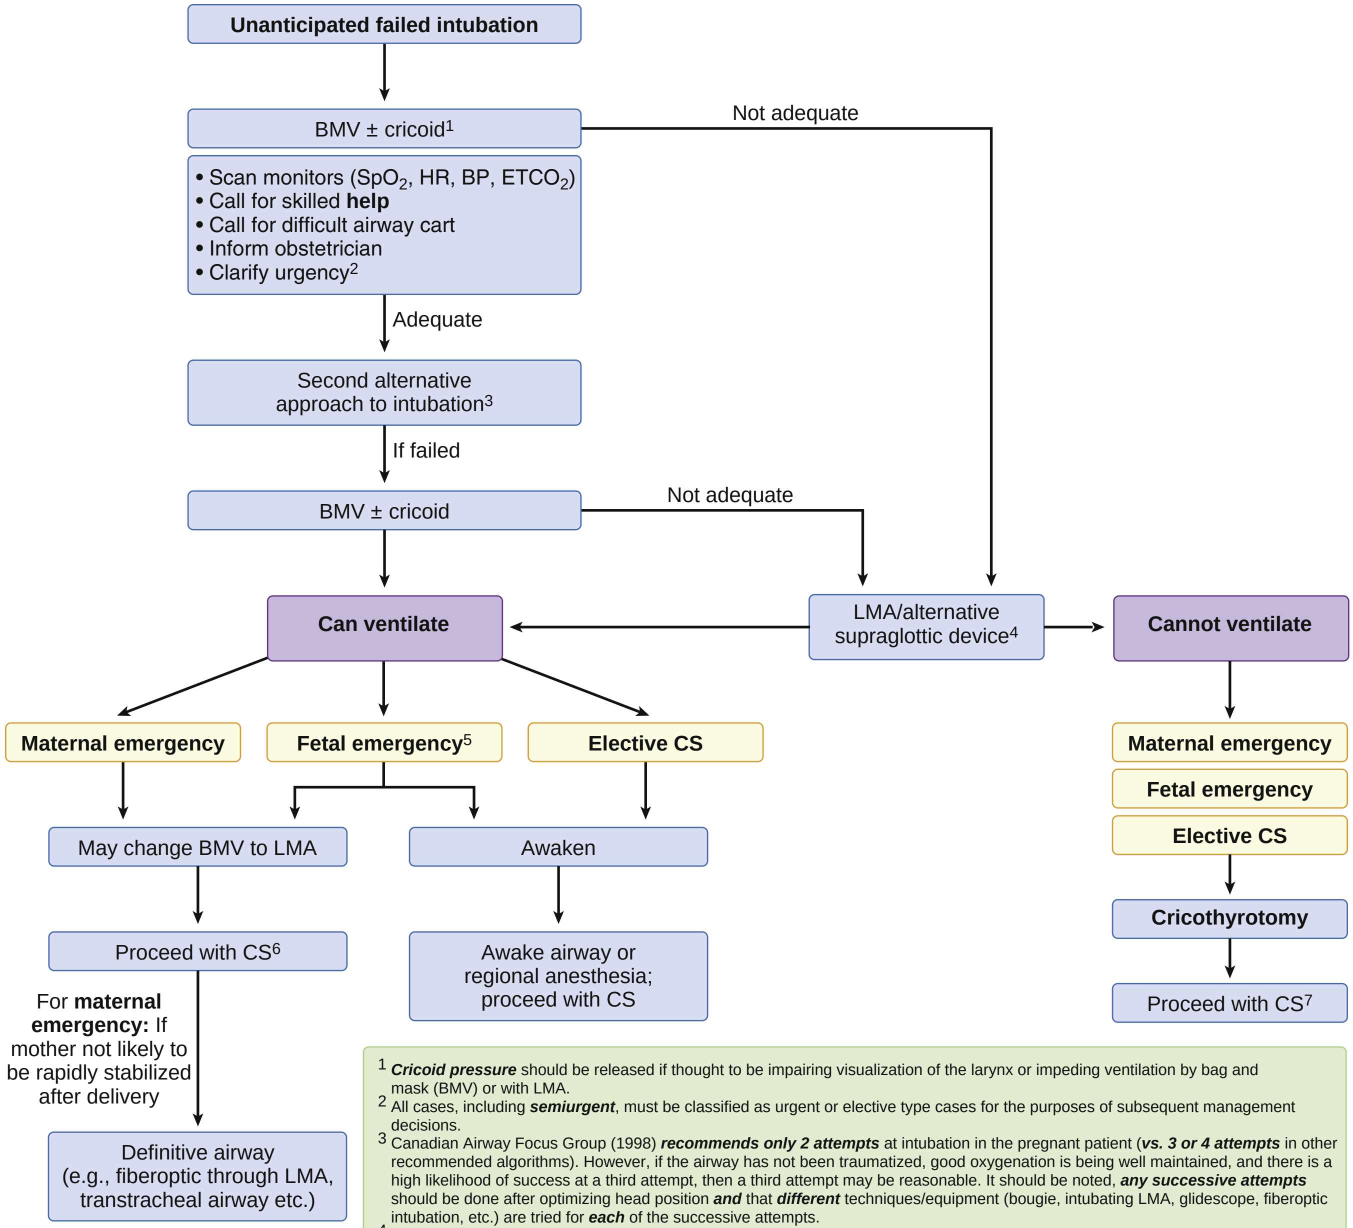
COMBINED SPINAL-EPIDURAL ANESTHESIA

Use of a CSE for cesarean delivery may be optimal in some situations as it combines the benefits of the spinal and epidural techniques. This technique allows for the rapid onset of a dense reliable block while allowing the block time or height to be extended with use of the epidural catheter. A low-dose sequential CSE, a technique where a small intrathecal dose of local anesthetic is given followed by administration of epidural medications, can be used in patients with cardiac disease or patients with short stature.[177] Possible disadvantages of a CSE for surgical anesthesia include the presence of an untested catheter and the possibility of a misplaced or nonfunctioning epidural. More details regarding the CSE neuraxial block are discussed in the previous section on labor analgesia.

GENERAL ANESTHESIA

Although neuraxial anesthesia is typically preferred, in certain emergent situations (e.g., fetal bradycardia, maternal hemorrhage or coagulopathy, uterine rupture, maternal trauma) general anesthesia may be needed for cesarean delivery because of its rapid onset. In addition, it allows for a controlled airway, controlled ventilation, and in some scenarios such as massive hemorrhage, improved hemodynamic control and perhaps decreased maternal psychological stress in comparison to neuraxial anesthesia.

Appropriate equipment preparation, knowledge of patient comorbidities, airway examination, and familiarity with the difficult airway algorithm are necessary preparation for delivering a safe general anesthetic. The ASA difficult airway algorithm[178] has been modified slightly by some authors for use in the setting of cesarean delivery, and a previously published example is provided in Fig. 62.4. Clear, concise communication among all members of the perioperative team is especially critical in urgent or emergent situations to maximize patient safety and minimize procedural complications. Open lines of communication are



Unanticipated failed intubation

May change BMV to LMA
Awaken
Proceed with CS6
Awake airway or regional anesthesia; proceed with CS
For maternal emergency: If mother not likely to be rapidly stabilized after delivery
Definitive airway (e.g., fiberoptic through LMA, transtracheal airway etc.)
Maternal emergency
Fetal emergency
Elective CS
Cricothyrotomy
Proceed with CS7

[1] ***Cricoid pressure*** should be released if thought to be impairing visualization of the larynx or impeding ventilation by bag and mask (BMV) or with LMA.

[2] All cases, including ***semiurgent***, must be classified as urgent or elective type cases for the purposes of subsequent management decisions.

[3] Canadian Airway Focus Group (1998) ***recommends only 2 attempts*** at intubation in the pregnant patient (***vs. 3 or 4 attempts*** in other recommended algorithms). However, if the airway has not been traumatized, good oxygenation is being well maintained, and there is a high likelihood of success at a third attempt, then a third attempt may be reasonable. It should be noted, ***any successive attempts*** should be done after optimizing head position ***and*** that ***different*** techniques/equipment (bougie, intubating LMA, glidescope, fiberoptic intubation, etc.) are tried for ***each*** of the successive attempts.

[4] ***If initial BMV is inadequate but ventilation by LMA (classic or proseal) or alternative supraglottic device is adequate,*** might consider proceeding with CS directly if absolute emergency ***or*** only make second or third attempt at intubation ***if*** mother is at higher risk for aspiration and/or slow difficult CS is anticipated.

[5] In the event of a ***fetal emergency only*** and a situation in which mother can be ventilated, there are ***two options:*** one may proceed with unprotected airway for sake of fetus or if mother is at higher risk than usual for aspiration, desaturation, or subsequent failure to ventilate or loss of airway (recent large meal, morbidly obese, airway significantly traumatized in failed intubation attempts, etc.), one may choose to awaken the mother and proceed to regional anesthesia or awake airway. This latter course of action may clearly put the fetus at great risk but follows the principle of "Mother comes first."

[6] ***Anesthesia management details*** should be at the ***discretion*** of the anesthesiologist, bearing in mind his or her own practice and preference and any patient or obstetric issues unique to each case: (1) additional doses of succinylcholine or return to spontaneous ventilation, (2) choice of maintenance anesthetic agents, and (3) elective change to LMA or other supraglottic devices even if BMV remains easy and effective.

[7] ***In the three cannot-ventilate situations,*** maternal and fetal ***emergencies*** should proceed to CS immediately after ***transtracheal airway***. Arguably in ***elective*** CS, the fetus will be stressed by now and hence CS should also be seriously considered at this point.

Unanticipated difficult airway in obstetric patients: development of a new algorithm for formative assessment in high-fidelity simulation. *Anesthesiology*. 2012;117:883–897, with permission.)

essential around the time of induction of anesthesia, airway management, and surgical incision.

A rapid-sequence induction commences with preoxygenation, followed by the application of cricoid pressure and the administration of an intravenous induction drug (typically propofol) and a neuromuscular-blocking drug (typically succinylcholine or rocuronium). If endotracheal intubation fails, consider placement of a supraglottic airway device, such as a laryngeal mask airway (LMA), or ventilation with mask and cricoid pressure.[92] The LMA has a high success rate for placement in obstetric patients; however, it does not protect against aspiration of gastric contents and should be used primarily for rescue of a failed intubation. Of note, the LMA has been used without observed aspiration or presence of hypoxia in a prospective study of over 1000 lean, low-risk patients undergoing elective cesarean delivery.[179,180]

Complications as a result of general anesthesia for cesarean delivery can be more common than general anesthesia for other procedures. For example, although the overall risk of intraoperative awareness is estimated to be 1:19,000 general anesthetics, the awareness risk for cesarean delivery is estimated at 1:670 (1:380-1:1300).[181] Anesthesia-related mortality from airway difficulties may occur during emergence and in the recovery period,[182] as well as during induction. Improper monitoring, provider inexperience, emergent situations, and patient obesity all increase patient risk.[183] Emergent cesarean delivery requiring general anesthesia is an uncommon but predictable emergency that can be practiced by teams using simulation to improve performance.

Induction of Anesthesia: Intravenously Administered Drugs

Premedication with lidocaine or fentanyl is typically avoided in cesarean delivery to limit fetal exposure. In scenarios in which hemodynamic stability is prioritized, such as preeclampsia or heart disease, remifentanil 1 to 2 μg/kg or fast-acting antihypertensives such as esmolol or labetalol can be used.

Propofol is most commonly used for induction of general anesthesia for cesarean delivery and is able to induce unconsciousness in approximately 45 seconds. Sodium thiopental 4 to 6 mg/kg intravenously is still used in many countries for induction of anesthesia. Propofol can result in significant hypotension and has an umbilical artery (UA) to umbilical vein (UV) ratio of 0.7.[184] Propofol administration does not affect neonatal Apgar scores with typical intravenous induction doses (2-2.5 mg/kg), but repeated or larger cumulative doses (9 mg/kg) are associated with significant newborn depression.[185]

Etomidate is quick acting and its rapid hydrolysis results in a relatively short duration of action. Unlike propofol and thiopental, etomidate has minimal direct effects on maternal hemodynamics and significant hypertension can occur when etomidate is used without adjuvant premedication in the healthy parturient. Etomidate has higher rates of nausea and vomiting and can increase risk for seizures in patients with decreased seizure threshold. At typical induction doses (0.3 mg/kg), decreased neonatal cortisol production for less than 6 hours was noted with unclear clinical significance.[186]

Ketamine inhibits the *N*-methyl-D-aspartate receptor and has analgesic, amnestic, and hypnotic properties with minimal respiratory depression effects. At typical induction doses (1-1.5 mg/kg), ketamine causes central stimulation of the sympathetic nervous system and inhibits the reuptake of norepinephrine. This helps maintain arterial pressure, heart rate, and cardiac output but could result in hypertension in the preeclamptic patient. It is an ideal choice for a pregnant woman in hemodynamic compromise resulting from bleeding. No neonatal depression is observed with standard induction dosing.[187] Larger doses can increase uterine tone, reduce uterine arterial perfusion, and lower maternal seizure threshold. In certain situations, ketamine may be used in smaller intravenous doses (<0.25 mg/kg) as a profound analgesic, but often causes unwanted hallucinations, which can be reduced with coadministration of benzodiazepines. Care should be taken if used for analgesia and conscious sedation so that repeated dosing does not result in loss of consciousness with an unprotected airway increasing the risk for pulmonary aspiration.

Muscle Relaxants

Uterine muscle tone is not affected by skeletal muscle relaxants, and in standard doses all classes of muscle relaxants are poorly transferred to the fetus. Succinylcholine 1 to 1.5 mg/kg intravenously has rapid onset (30-45 seconds) and short duration of action. After administration, it is hydrolyzed in the plasma by pseudocholinesterase and only small amounts cross to the fetus because it is highly ionized and poorly lipid soluble. It is undetectable in umbilical cord samples unless larger maternal doses are administered (2-3 mg/kg), and exceedingly high maternal doses (10 mg/kg) are needed to inadvertently create neonatal neuromuscular blockade.[188] After succinylcholine administration, maternal muscle strength should always be monitored because prolonged weakness can occur if the hydrolytic enzyme has a reduced plasma concentration or an atypical form (such as in pseudocholinesterase deficiency) or if muscle weakness is exacerbated by prior administration of magnesium sulfate.

Rocuronium may be considered as an alternative to succinylcholine for muscle relaxation. It allows adequate relaxation for endotracheal intubation in less than 60 seconds at intravenous doses of 0.9 to 1.2 mg/kg.[189,190] This is an attractive alternative to succinylcholine because even after an intravenous intubating dose of 0.9 to 1.2 mg/kg body weight, the neuromuscular blocking effect can rapidly be reversed by a large intravenous dose of sugammadex (12-16 mg/kg body weight), which makes the total duration of action shorter than after an equipotent dose of succinylcholine. Like succinylcholine, nondepolarizing muscle relaxants do not cross to the fetal circulation in amounts that would cause neonatal weakness.[191] However, if large doses of nondepolarizing neuromuscular blockers are given over long periods, neonatal neuromuscular weakness can occur. Although cholinesterase inhibitors may be administered to the neonate, treatment is primarily respiratory support until the drug is eliminated. Neonatal elimination of muscle relaxants may take significantly longer than adult elimination.

In the case of administration of magnesium sulfate, a distinct potentiation of the effect of any nondepolarizing agents occurs, with subsequently prolonged recovery time. The choice and dosing of neuromuscular blocking drugs should therefore take into account the interaction with magnesium sulfate and the potential risk for muscle weakness resulting from residual neuromuscular block in the recovery room or postanesthesia care unit. As a consequence, neuromuscular monitoring based on an objective monitoring technique should be used to assess neuromuscular function in these patients.

Maintenance of General Anesthesia

After induction, general anesthesia is most frequently maintained with a volatile anesthetic agent with or without N_2O. Volatile anesthetics help reduce the incidence of maternal recall. Although the MAC to prevent movement in response to a painful stimulus is reduced in pregnancy, electroencephalographic evidence suggests that anesthetic effects of a halogenated agent on the brain are similar in the pregnant and nonpregnant state.[42] Volatile anesthetics are highly lipid soluble, have a low molecular weight, and are readily transferred to the fetus. Fetal concentrations depend on both the maternal plasma concentrations and duration of the anesthetic before delivery. After delivery, opioids, propofol, benzodiazepines, N_2O, or a combination are administered and the halogenated anesthetic is typically reduced to 0.5 MAC. These additional intravenous drugs are administered only after the cord is clamped to prevent any transfer to the neonate and associated respiratory depression. Use of only volatile anesthetics at higher concentrations is associated with increased blood loss secondary to uterine atony because all volatile anesthetics negatively impact uterine muscle contraction.[192]

General anesthesia for cesarean delivery is frequently used in cases of fetal distress because it is rapid and reliable. Clearly, a fetus depressed before delivery often becomes a depressed neonate. A Cochrane systematic review of uncomplicated cesarean deliveries comparing regional and general anesthesia concluded that “No significant difference was seen in terms of neonatal Apgar scores of six or less and of four or less at one and five minutes,” and the need for neonatal resuscitation with oxygen was not different between the two groups.[193] The review noted neither method of anesthesia was superior for neonatal outcome.

If large concentrations of volatile anesthetics are administered for a prolonged time, neonatal flaccidity, cardiorespiratory depression, and decreased tone may be anticipated. If neonatal depression is due to volatile anesthetics, the infant should respond to assisted ventilation to facilitate exhalation of the anesthetics. Consequently, physicians able to assist with neonatal ventilation should be present at all cesarean deliveries performed under general anesthesia. In addition, communication to all perioperative physicians is critical if extended anesthetic time is anticipated before delivery. A prolonged time under general anesthesia prior to delivery can be anticipated by obstetricians in some patients such as those with significant scar tissue from prior surgeries or extreme obesity. Neonates may experience greater benefit from regional anesthesia in these scenarios.

Postcesarean Pain Control and Recovery

Pain after cesarean delivery is variable in intensity among patients. Excellent pain control after cesarean delivery can lead to improved maternal functional ability, enhanced recovery, decreased persistent opioid use, decreased incidence of chronic pain, and improved maternal-infant bonding.[194,195] Postoperative pain control can be achieved with multimodal therapy. A typical strategy consists of neuraxial opioids, scheduled nonsteroidal antiinflammatory drugs, scheduled acetaminophen, and limited systemic opioids. Neuraxial opioids are considered the “gold standard” for effective postoperative pain control and have been shown to be superior to systemic opioids[196] and transversus abdominis plane (TAP) block.[197] Pruritus, nausea and vomiting, and respiratory depression are opioid-related side effects.

Alternative modes of analgesia are available and can be utilized if neuraxial opioids are contraindicated or general anesthesia is utilized. Peripheral nerve blocks include TAP, quadratus lumborum, and ilioinguinal-iliohypogastric blocks (see Chapter 46). A meta-analysis demonstrated TAP blocks significantly reduced postoperative pain intensity and decreased opioid consumption in women who did not receive intrathecal morphine.[197] Quadratus lumborum blocks are gaining popularity in cesarean deliveries and may have advantages over TAP blocks. A randomized controlled trial comparing quadratus lumborum with TAP blocks found a reduction in morphine use in the quadratus lumborum group.[198] Continuous wound infiltration with local anesthetics may also be beneficial for patients having general anesthesia.[199]

Complications of Regional Anesthesia

In addition to the neuraxial drug–related complications noted previously, administration of neuraxial anesthesia can result in complications including PDPH, epidural or spinal hematoma, neurologic injury, or total spinal anesthesia (see also Chapter 45).

POSTDURAL PUNCTURE HEADACHE

The earliest experiments with spinal cocaine resulted in severe PDPH. Leakage of spinal fluid is thought to result in vascular hyperemia, migraine physiology, and traction on pain-sensitive fibers. The headache associated with PDPH is postural in that it is worsened by standing and relieved by lying down. The incidence, severity, and duration of PDPH are related to the size of the needle and the shape of the tip. Spinal needles used for CSE technique range from 25 to 29 gauge and result in an incidence of PDPH of less than 1%.[200,201] Epidural catheters are most commonly placed through a 17- or 18-gauge blunt-tipped needle. The incidence of unintentional dural puncture during labor epidural placement is 1% to 1.5%.[202,203] The incidence of headache after an unintentional dural puncture with an epidural needle is reported at 30% to 80%.[200]

In the setting of an unintended dural puncture with an epidural needle, an intrathecal catheter may be threaded, or the epidural needle may be removed and replaced at a different interspace. If an intrathecal catheter is placed, unintentional injection of an epidural anesthetic dose must be carefully avoided. Placement of the intrathecal catheter can provide labor analgesia and alleviates the need for multiple repeat epidural attempts with the potential of a second accidental dural puncture.[204]

When diagnosing a PDPH, it is important to consider other causes of headache in the postpartum period. Assessing the patient for fever and nuchal rigidity is important because postdural-puncture meningitis can initially present with a headache. Early treatment of meningitis is important to prevent morbidity and mortality. Likewise, assessing the patient for hypertension is important to detect postpartum preeclampsia, which can present with a headache and requires rapid treatment to prevent maternal stroke. A thorough neurologic exam should also be performed because cerebral venous thrombosis, cranial subdural hematoma, and ischemic or hemorrhagic stroke can present as a postpartum headache. Benign headaches from tension, dehydration, sleep deprivation, caffeine withdrawal, or migraine should be considered prior to treating a PDPH.

PDPH is often initially treated conservatively. Given the similarity of symptoms to those of migraine headache, PDPHs have been treated with drugs that are useful in migraine with variable success. Caffeine can be minimally effective to treat the pain of a PDPH in the short-term likely because of its vasoconstrictive effects.[205]

If the symptoms are severe enough to limit a patient's activity then an epidural blood patch (EBP) should be considered. If there is evidence of cranial nerve involvement such as diplopia, then an EBP should be performed immediately. Note that the symptom of muffled hearing is common with PDPH and thought not to be a result of cranial nerve involvement, but instead, a decrease in middle ear pressure because the middle ear fluid is connected to the cranial CSF via the cochlear aqueduct. In one retrospective review of an EBP database, all parturients with PDPH experience relief after the EBP but 16.8% required two and 1.5% required three EBPs.[203] Controversy exists over the optimum volume of blood to be injected during an EBP but studies support an attempt to administer 20 mL of autologous blood during the procedure.[203,206]

EPIDURAL HEMATOMA

The epidural space is highly vascular, and vessels can be punctured during neuraxial needle placement or catheter threading. However, with normal platelets and coagulation factors, epidural hematoma is extremely uncommon. The Serious Complication Repository (SCORE) Project reported the incidence of epidural hematoma to be 1 in 251,463 (95% CI, 1:46,090-1:10,142,861)[207] and another large study found no cases of hematoma out of 79,837 obstetric epidural placements with an estimated upper limit of 1 in 4.6×10^{-5}.[208] Although rare, back pain and persistent motor blockade are potential signs of epidural hematoma and should be thoroughly evaluated. Patients should be followed postpartum until complete resolution of the epidural blockade. Patients are at increased risk for developing a hematoma in the setting of coagulopathy and anticoagulation use. Following the guidelines of the American Society of Regional Anesthesia (ASRA) with consideration for the Society for Obstetric Anesthesia and Perinatology (SOAP) Consensus Statement (Fig. 62.5) regarding anticoagulation therapy and neuraxial anesthesia in the obstetric patient is recommended.[209,210] If an epidural hematoma is suspected, imaging should occur immediately with the goal of prompt epidural hematoma evacuation to avoid permanent neurologic injury.

NEUROLOGIC INJURY

Direct spinal cord damage from an epidural or spinal needle placed for labor is exceedingly rare because obstetric neuraxial anesthesia procedures are typically performed below the level of the conus medullaris. It has, however, been described with spinal anesthesia attempts performed at unintentionally high levels resulting in spinal cord syrinx formation with injection. In a series of seven such cases, all of the patients who experienced this complication described pain on injection.[211] Therefore if a patient complains of pain on injection of neuraxial medication, the proceduralist should stop injecting *immediately*.

Overall, damage attributed to direct neurologic injury has been estimated at 0.6 in 100,000 with epidural and 3 in 100,000 with spinal analgesia.[212-214] Data from the SCORE project show an incidence of serious neurologic injury in the postpartum period to be 1 in 11,389 (95% CI, 1:7828-1:17,281) but only 1:35,923 (95% CI, 1:17,805-1:91,244) are thought to be related to anesthesia.[207]

Evaluating postpartum lumbosacral neuropathies is a common part of an obstetric anesthesia practice. A large prospective study showed that 0.92% of women experienced postpartum lumbosacral or lower extremity nerve injury, the incidence of which was associated with nulliparity and prolonged second stage of labor, but not epidural analgesia use.[215] Femoral and lateral femoral cutaneous neuropathies were the most common, likely from women in extreme hip flexion in the semi-Fowler position. Encouraging women to straighten their legs between pushes can restore blood flow to the nerves of the lumbar plexus. Most of these peripheral neuropathies heal with time but outpatient follow up with a neurologist to follow the course and rule out other causes should be considered.

LOCAL ANESTHETIC SYSTEMIC TOXICITY

The accidental injection of intravascular local anesthetic could result in the development of local anesthetic systemic toxicity (LAST). The development of LAST is rare in obstetrics secondary to the dilute local anesthetic solutions utilized for epidural analgesia and the use of lidocaine and 2-chloroprocaine for operative delivery. The SCORE project reported one maternal cardiac arrest from LAST after a TAP block.[207] LAST as a result of TAP blocks in obstetrics has been reported multiple times and the use of no greater than 0.25% concentration of bupivacaine, adding 1:200,000 epinephrine, administering no greater than a 20 mL volume on each side, placement under ultrasound to be sure the injection is not intraperitoneal, and careful, slow, injection with intermittent aspiration is recommended.[216] The treatment of LAST includes the administration of lipid emulsion in addition to basic and advanced cardiac life support.[217]

TOTAL SPINAL BLOCK

A total spinal block is a rare and life-threatening complication that occurs after excessive cephalic spread of local anesthetic in the CSF resulting in severe respiratory and cardiac compromise. It can occur after a single spinal injection or as a result of inadvertent intrathecal spread of epidural

medication. Risk factors associated with high neuraxial blockade include obesity, spinal technique after failed epidural anesthesia, short stature, epidural after an accidental dural puncture, and spinal deformity.[207]

OTHER COMPLICATIONS

When strict aseptic technique is used, infection is uncommon with spinal and epidural anesthesia.[218,219] Nonetheless, postdural puncture meningitis and epidural abscess has been described[220] and the ASA and ASRA recommend the following aseptic techniques during placement of neuraxial needles and catheter: removal of jewelry, hand washing, wearing of caps, wearing of masks covering both mouth and nose, use of sterile gloves, use of an antiseptic solution (e.g., chlorhexidine with alcohol), and sterile draping of the patient.[221,222]

Postpartum back pain is common after childbirth regardless of whether neuraxial analgesia has been used. However, no evidence indicates that back pain is more common when neuraxial analgesia is used for labor. Several trials have identified an association between increased maternal temperature and epidural use as a secondary outcome.[223] Attribution of causality is difficult in this setting and the etiology is not well understood but likely involves noninfectious inflammation.[223,224]

Maternal Comorbidities

HYPERTENSIVE DISORDERS

Hypertensive disorders of pregnancy are among the most common causes of maternal morbidity and are associated with more frequent rates of maternal and fetal mortality.[225] Hypertensive disorders of pregnancy complicate 5% to 10% of pregnancies worldwide and preeclampsia is diagnosed in 3% of pregnancies.[225] The World Health Organization (WHO) has identified hypertension as the second most common cause of maternal death, accounting for 14% of mortality associated with pregnancy.[226] Chronic hypertension may precede pregnancy and may or may not be complicated by superimposed preeclampsia.

Although some variations exist in hypertensive definitions worldwide, the following are used in the United States by the ACOG based on a working group in 2013.[227] Gestational hypertension is defined as the onset of hypertension (systolic blood pressure [SBP] >140 mm Hg or diastolic blood pressure [DBP] >90 mm Hg) after 20 weeks' gestation in a previously normotensive parturient without proteinuria. Preeclampsia is defined as hypertension (SBP >140 mm Hg or DBP >90 mm Hg) after 20 weeks' gestation associated with proteinuria. Preeclampsia is diagnosed when urine protein excretion is greater than 300 mg in a 24 hour period or, alternatively, there is a protein/creatinine ratio of at least 0.3. In 2013, massive proteinuria (>5 g in 24 hours) and fetal growth restriction were eliminated as considerations of severe preeclampsia. In addition, the term *mild preeclampsia* is no longer used. Now only *preeclampsia* or *preeclampsia with severe features* are defined. Severe features of preeclampsia include an SBP of 160 mm Hg or greater or DBP of 110 mm Hg or greater on two separate occasions at least 4 hours apart while on bed rest; thrombocytopenia (platelet count less than 100,000/μL); impaired liver function with twice normal concentrations of liver enzymes; right upper quadrant pain; progressive renal insufficiency with serum creatinine greater than 1.1 mg/dL or a doubling of serum creatinine without other known renal disease; pulmonary edema; and new onset cerebral or visual abnormalities. In the absence of proteinuria, preeclampsia can be diagnosed with new onset hypertension (as previously defined) and the presence of a severe feature.[227]

The combination of hemolysis, elevated liver enzyme, and low platelet count (HELLP) is considered preeclampsia with HELLP syndrome. Eclampsia is preeclampsia complicated by seizure activity. The incidence of preeclampsia has increased likely as a result of increases in maternal age and obesity, whereas the risk for eclampsia has decreased because of improved prenatal care and the use of prophylactic intravenous magnesium.[225,228] The cause of preeclampsia is not known, but it is generally thought that placental insufficiency through a cascade of antiangiogenic factors (e.g., s-Flt) eventually leads to maternal generalized endothelial dysfunction. The cause of the placental insufficiency is likely variable and could include maternal or paternal genetics and/or environmental factors. Patients with preeclampsia have an elevated risk for cerebral hemorrhage, pulmonary edema, and coagulopathy. Current guidelines recommend treating SBP more than 160 mm Hg for prevention of intracerebral hemorrhage.[227] Initial treatment typically includes intravenous labetalol, hydralazine, and/or oral nifedipine.[229] Other considerations are increased airway edema with associated difficulty of intubation and increased rates of postpartum atony related to the use of magnesium sulfate. Methylergonovine (Methergine) should be used cautiously in patients with preeclampsia because it may lead to hypertensive crisis. Women with preeclampsia can be sensitive to both endogenous and exogenous catecholamines. Therefore careful administration of adrenergic agents is recommended.

Women with a diagnosis of preeclampsia should have their platelet count checked before initiation of regional anesthesia or removal of an epidural catheter. Coagulopathy is a contraindication to regional anesthesia. Although the risk for spinal hematoma is lower in pregnant women than in the elderly,[213] one study found 68% of patients who had spinal hematomas after neuraxial blockade had preexisting coagulopathy.[230] Lastly, despite the concerns for hypotension, spinal anesthesia is safe to administer in preeclamptic patients.[231,332]

COAGULOPATHIES

Thrombocytopenia complicates 10% of pregnancies as a result of several etiologic factors.[233,234] Thrombocytopenia may be preexisting or can develop as a result of the pregnancy. As discussed earlier, thrombocytopenia that develops after 20 weeks' gestation may be a sign of preeclampsia with HELLP syndrome. However, most thrombocytopenia that develops in pregnancy is benign, gestational thrombocytopenia. The platelet count is expected to decrease by approximately 10% in a normal pregnancy.[235]

Autoimmune thrombocytopenia, antiphospholipid syndrome, and liver disease are less common.[234] Glucocorticoids and IV immunoglobulin can be used to elevate platelet counts in certain types of severe disease but require several days to be effective.[236] No platelet count is universally accepted as safe for epidural placement. Most anesthesiologists agree that placement of an epidural in the setting of a platelet count greater than 100,000/mm^3 is safe and recent literature suggests lower thresholds may be safe. A retrospective observational study of cases from 14 diverse institutions combined with a systematic review evaluated 1524 parturients with a platelet count of less than 100,000/mm^3 and found the upper bound of the 95% CI for the risk of epidural hematoma for a platelet count of 0 to 49,000/mm^3 is 11%, 50,000 to 69,000/mm^3 is 3%, and 70,000 to 100,000/mm^3 is 0.2%.[237] Of note, no cases of epidural hematomas requiring surgical decompression were identified in this cohort.

Women with von Willebrand disease are at increased risk for bleeding intrapartum and postpartum.[238] Prophylactic treatment is recommended for women with von Willebrand factor (vWF) less than 50 international units/dL. Because of the multiple types and subtypes of von Willebrand disease that have different responses to therapy, it is imperative that hematologic studies be part of the management to help guide the most appropriate therapy. In type I von Willebrand disease, a partial reduction in the quantity of vWF is seen. Women with type I von Willebrand disease usually do not need prophylactic treatment because their vWF typically rises in the third trimester of pregnancy to greater than 50 international units/dL. Desmopressin can be used in women with type 1 von Willebrand disease to release vWF. Type 2 von Willebrand disease is characterized by a defect in the function of vWF, and facilitation of release is not helpful. Parturients with type 3 von Willebrand disease almost always require replacement of vWF before delivery, because they have almost no intrinsic vWF. Although concern should be elevated for epidural hematoma, women with normal factor levels can have regional anesthesia in the setting of a normal platelet count.[239]

Deep venous thrombosis (DVT) and pulmonary embolism are more common in pregnancy as a result of hormonal changes. Significant risk factors are factor V Leiden, prothrombin G20210A, protein S, protein C and antithrombin deficiency, and antiphospholipid antibodies.[240] Patients diagnosed with DVT or pulmonary embolism in pregnancy will need prolonged anticoagulation and will require delivery planning with a brief anticoagulation hiatus for regional anesthesia and delivery. Factor V Leiden is an abnormal variant of factor V that acts as a cofactor that allows activation of thrombin by factor Xa. The factor V Leiden variant cannot be easily degraded by activated protein C and thus leads to hypercoagulability. Patients with a factor V Leiden abnormality may be maintained on anticoagulants for prophylaxis or treatment of DVT and appropriate cessation of anticoagulants must occur prior to placement of neuraxial blockade.[210,241]

OBESITY

Maternal obesity (prepregnancy body mass index ≥30 kg/m^2) and metabolic syndrome cause gestational diabetes, newborn hyperglycemia, larger babies, prolonged labor, and cesarean delivery.[68,242] Cesarean delivery for obese women holds greater risk of mortality.[243,244] Sleep apnea is more common in obese parturients and is a risk factor for hypoventilation after treatment with systemic opioids and difficult tracheal intubation when general anesthesia is required. Morbidly obese parturients are at increased risk of longer first stage of labor and operative delivery.[245] Epidural anesthesia placement in obese parturients is more difficult and takes longer and they are more likely to require a repeat procedure due to inadequate pain control or failure to achieve bilateral sensory blockade.[245,246] An early anesthesia consultation is advised for morbidly obese women regardless of planned delivery mode.

CARDIAC DISEASE

The leading cause of maternal mortality in the United States is cardiac disease.[156] In planning an anesthetic for a delivery in a woman with congenital or acquired heart disease, the anesthesia provider must take into consideration the patient's cardiac lesion or disease state; the normal physiologic changes of pregnancy, labor, and delivery; and the hemodynamic changes of the anesthetic itself. During pregnancy, labor, and delivery, regurgitant valvular lesions are generally tolerated better than stenotic valvular lesions.[247] Pulmonary hypertension, severe left ventricular outflow tract obstruction, moderate to severe mitral stenosis, and cyanotic congenital heart disease all carry significant risk for maternal morbidity and mortality. Multiple risk factors have been identified as increasing a woman's likelihood of major morbidity and mortality including prior stroke, low ejection fraction, aortopathy, and heart failure symptoms. The American Heart Association, the American College of Cardiology, and the European Society of Cardiology have classified certain conditions or cardiac lesions as high maternal or fetal risk.[248-251] In comparison to other risk stratification systems,[251,252] the modified WHO risk stratification system appears to perform best in predicting maternal morbidity or mortality during pregnancy and delivery.[253] Such risk stratification informs the obstetric and anesthesia team as to what resources a parturient with heart disease may require, and thereby whether they need to transfer to a tertiary care facility for delivery.

Increased monitoring including 5-lead ECG or intra-arterial blood pressure monitoring may be necessary for labor, especially in women who have a history of tachyarrhythmia or are hemodynamically tenuous. Epidural labor analgesia is recommended for women with heart disease to decrease catecholamine release and eliminate the increased cardiac output and tachycardia attributable to labor pain. The afterload reduction that occurs with epidural analgesia should be followed closely and may need to be countered with a carefully titrated α-adrenergic agonist to prevent tachycardia and ischemia. When cesarean delivery is indicated, it is important to tailor the anesthetic technique to each individual patient. Regional anesthesia is not necessarily contraindicated and should be considered for most patients.

ANTICOAGULATION

Anticoagulation is often required for women with artificial heart valves, certain types of congenital heart disease, pulmonary hypertension, and cardiomyopathy. It is necessary to carefully time stopping anticoagulation to allow for epidural placement and birth while restarting before a clot can form. For this reason, women are usually maintained on heparin at the end of pregnancy, pending delivery, because of its quick offset. If IV unfractionated heparin was used, it should be stopped 4 to 6 hours before the procedure and normal coagulation status (PTT or activated clotting time [ACT]) documented before neuraxial instrumentation or removal of an epidural catheter.[209,210] If a parturient is maintained on subcutaneous unfractionated heparin, the time interval required to stop prior to a neuraxial procedure corresponds to the dose and activated partial thromboplastin time (aPTT) that can be measured (see Fig. 62.5*A*). If conversion to intravenous heparin cannot take place before labor, warfarin should be stopped and neuraxial analgesia deferred until the PT is within normal limits and the INR is documented at less than 1.5. Low-molecular-weight heparin (LMWH) has been used frequently for prophylaxis of DVT in pregnancy. Unlike unfractionated heparin, the anticoagulant effects of LMWH cannot be reliably measured, and it is not reversible with protamine. It is recommended to wait a prespecified time interval prior to performing a neuraxial procedure, rather than ordering laboratory testing. The decision to place or remove a neuraxial block in a patient on LMWH should correspond to the individual dose and total daily dose (see Fig. 62.5*B*).[210] Nonsteroidal antiinflammatory drugs do not in themselves increase risk for spinal hematoma, but can increase risk in combination with other anticoagulants.[209] If labor begins before neuraxial analgesia can safely be given, intravenous remifentanil and N_2O are alternatives in some settings.[254,255]

PULMONARY DISEASE

As previously detailed in the section on pulmonary changes, adaptations in the respiratory system are required to meet the metabolic demands of the mother and fetus with increases in minute ventilation, decreased O_2 reserve, and increased airway edema most notable.

Asthma is characterized by reversible airway obstruction, airway hyperresponsiveness, and airway inflammation. It is the most common respiratory disease in pregnancy with considerable maternal morbidity. A prospective trial of 1739 pregnant asthmatic patients found those with mild asthma had an exacerbation rate of 12.6% and a hospitalization rate of 2.3%, those with moderate asthma had an exacerbation rate of 25.7% and a hospitalization rate of 6.8%, and those with severe asthma had an exacerbation rate of 51.9% and a hospitalization rate of 26.9%.[256] Bronchodilators and antiinflammatory drugs are generally safe for the fetus and should be used in pregnancy to control asthma. A meta-analysis found that maternal asthma was associated with increased risk of maternal and placental complications including cesarean delivery, gestational diabetes, abruption, and hemorrhage.[257]

Community-acquired pneumonia is the most common nonobstetric infectious complication that results in maternal death.[258] During the 2009 H1N1 influenza epidemic, pregnant women were disproportionately affected. Pregnant women were at increased risk for hospitalization, ICU admission, and death.[259] Preterm delivery is a significant complication of pneumonia even in the setting of antibiotic therapy. Aspiration of gastric contents is also more common during endotracheal intubation in pregnant than in nonpregnant patients because of laxity of the gastroesophageal junction combined with anatomic changes from the expanding uterus.[260] Strict fasting recommendations, rapid-sequence tracheal intubation, and antacids are used before general anesthesia in pregnancy.

Cystic fibrosis is a common autosomal-dominant disorder in women of northern European origin. With improved medical care, women with cystic fibrosis are living to reproductive years and beyond. Pregnancy is uncommon in women with cystic fibrosis (216 pregnancies in 24,000 women), but when it occurs, careful multidisciplinary care is required.[261] The disease is caused by a mutation in the cystic fibrous membrane conductance regulator in epithelial cells, which causes abnormalities in the lungs, pancreas, intestines, and hepatobiliary systems. The major issues in pregnancy are restrictive lung disease and diabetes.

NEUROLOGIC DISORDERS

Multiple sclerosis is a neuroinflammatory disorder that disproportionately affects young women. Pregnancy is associated with a decrease in the incidence of relapse, although the rate of relapse during the first 3 months postpartum is increased in comparison with the year before pregnancy.[262] Multiple sclerosis is a disease of demyelination, and thus theoretic concern exists that local anesthetic toxicity may be enhanced. Cases of worsening symptoms after regional anesthesia have been reported; however, it is hard to impute causality in a relapsing and remitting disease. Nevertheless, the lowest effective concentration possible should be given and vasoconstrictive agents should be avoided. Some recommend epidural instead of intrathecal local anesthetic administration when possible.[263]

Neurofibromatosis is an autosomal-dominant disorder that occurs in 1 in 3000 individuals, with variable manifestations. It is characterized by café-au-lait lesions on the skin, cutaneous neurofibromas, Lisch nodules of the iris, bone abnormalities, and tumors of the spinal cord and cranial nerves.[261] Neurofibromas often grow in pregnancy. Disagreement exists as to whether neuraxial anesthesia is contraindicated in women with neurofibromatosis because of the incidence of vascular spinal tumors. Epidural hematoma has been reported in a woman with neurofibromatosis in the setting of a spinal tumor.[264] The hormonal changes of pregnancy may cause tumor growth, and a knowledge of lesion location and current clinical symptoms is needed to avoid instrumentation of tumors and safely deliver neuraxial anesthesia.[265]

OPIOID DEPENDENCE

Opioid use is increasing in the United States and opioid abuse is now epidemic. Opioids are commonly prescribed to women during pregnancy and one study found 14% of American women were prescribed opioids at least once during pregnancy.[266] Of concern, opioid abuse or dependence during pregnancy is associated with obstetrical morbidity and mortality including abruption, increased hospital length of stay, oligohydramnios, and maternal death.[267] In addition, extended opioid use or dependence can result in neonatal abstinence syndrome (NAS) in the neonate, which often requires medication and extended hospital stay. NAS is characterized by hyperirritability of the central nervous system and dysfunction of the autonomic nervous system, gastrointestinal system, and respiratory system. Methadone is often utilized for treatment of opioid dependence during pregnancy but is associated with NAS. Buprenorphine is increasingly utilized in pregnancy and although it is associated with NAS, the symptoms may be milder in buprenorphine-exposed neonates.[268] Peripartum pain management can be challenging in patients with opioid dependence and multimodal therapy is recommended for both vaginal and cesarean delivery.

Anesthesia for Malpresentation and External Cephalic Version

Breech presentation occurs when the fetal buttocks or lower extremities are the presenting part in the pelvis and is the most common abnormal presentation in pregnancy. Approximately onequarter of pregnancies are in a breech presentation before 28 weeks but most change to vertex by 34 weeks' gestation. Approximately 3% to 4% of fetuses are breech presentation at term.[269] Breech presentations can sometimes be converted to vertex by an external cephalic version. Neuraxial anesthesia is associated with a higher success rate for external cephalic version.[270] Anesthetic rather than analgesic concentrations allow for relaxation of abdominal wall musculature, which may help the obstetrician[271]; however, a recent randomized, double-blind trial found escalating doses of bupivacaine (2.5, 5, 7.5, and 10 mg) did not change the success rate of external cephalic version.[272] External cephalic version has an overall success rate (all gestational ages) of approximately 60%, with risks for abruption, fetal bradycardia, rupture of membranes, and need for emergent delivery. For these reasons, an anesthesia provider should be immediately available when external cephalic version is performed in the event an emergent delivery is needed.

Higher order multiple births are frequently delivered by cesarean delivery because of the likelihood of cord entanglement and possibility of head entrapment. Twin pregnancy can be delivered vaginally but may present difficulties at delivery. If the second twin is not in the vertex position, an epidural can provide abdominal muscle relaxation and analgesia to allow for version or manual extraction.[273-275] In addition, it provides analgesia and perineal relaxation for instrumented delivery if needed, and the ability for conversion to cesarean delivery if the second twin becomes distressed or is unable to be delivered vaginally. The same considerations apply for external cephalic version of a singleton breech presentation.

Obstetric Emergencies

A variety of emergent conditions may manifest during the care of obstetric patients. These urgent situations frequently involve maternal hemorrhage, fetal distress, or both. To optimize the clinical outcome, prior preparation and excellent communication among all members of the peripartum care team are essential.

MATERNAL MORTALITY

An estimated 303,000 maternal deaths occurred worldwide in 2015.[276] Developing regions account for approximately 99% of the global maternal deaths. Accurate measurement of maternal mortality is challenging and many deaths go uncounted. Hemorrhage, hypertensive disorders of pregnancy, and sepsis are the leading causes of maternal deaths worldwide.[226] Although globally the maternal mortality ratio is declining, it is increasing in the United States[156,226] for reasons that have not been completely understood. However, it is likely the incidence of maternal death is increasing as a result of an increase in maternal age, obesity, births by cesarean delivery, and prepregnancy comorbid conditions.

A study examined pregnancy-related deaths from 2006 to 2010 in the United States using data from the Pregnancy Mortality Surveillance System and found the number one cause of death to be cardiovascular conditions (14.6%). Other causes of pregnancy-related death included infection (13.6%), noncardiovascular medical conditions (12.7%), cardiomyopathy (11.8%), hemorrhage (11.4%), thrombotic pulmonary or other embolism (9.6%), and hypertensive disorders of pregnancy (9.4%). Of concern, non-Hispanic black women have the highest risk of dying from pregnancy complications.[156] This study also found deaths due to cardiovascular conditions and infection have increased while deaths from hemorrhage, hypertensive diseases of pregnancy, embolism, and anesthetic complications declined compared to previous time periods examined.[156]

The UK Confidential Enquiry into Maternal Deaths and Morbidity found from 2014 to 2016, Asian women had a twofold and black women had a fivefold difference in maternal mortality compared to white women.[277] During this time period, the leading causes of direct maternal deaths included thromboembolisms, obstetric hemorrhage, and suicide. The majority (57%) of maternal deaths in the UK are related to indirect causes with cardiac disease being the largest single contributor. Sepsis is also a leading cause of maternal morbidity and mortality in the UK and United States.

To improve maternal patient safety, organizations and patient safety bundles have been created to prevent morbidity and mortality associated with postpartum hemorrhage, maternal venous thromboembolism, and severe hypertension in pregnancy.[278] When a comprehensive obstetric hemorrhage patient safety bundle was implemented, women with hemorrhage experienced a 20.8% reduction in severe maternal morbidity compared to a 1.2% reduction ($P < .0001$) in hospitals without bundle implementation.[279] As peripartum physicians, anesthesiologists can contribute to improved outcomes by implementing these patient safety bundle elements.

OBSTETRIC HEMORRHAGE

Hemorrhage during pregnancy carries significant morbidity and is a leading cause of maternal death worldwide.[226,280] In addition, the need for blood transfusion is the most common indicator of severe maternal morbidity based on 2008 to 2009 US peripartum hospitalization data.[281] Most of these hemorrhage-related deaths are preventable, and appropriate training, simulation, team communication, and education are all essential elements needed to improve patient outcome.[282,283] Common difficulties with hemorrhage management include inaccurate determination of blood loss, unrecognized hemorrhage risk factors, delayed intervention, and improper or inadequate transfusion of blood products. Various causes of peripartum hemorrhage and management of obstetric hemorrhage are discussed in greater detail in the following section.

Placenta Previa and Accreta

Placenta previa is diagnosed when the placenta is located low in the uterus and in front of the presenting fetus, either covering or encroaching on the cervical os. The incidence is approximately 0.5% of all pregnancies. Associated risk factors include advanced maternal age, assisted pregnancy, multiparity, prior placenta previa, and uterine scarring from infection or prior surgery. Placenta previa normally manifests as painless vaginal bleeding, with the first occurrence being self-limited. The diagnosis is confirmed or determined by ultrasonography. Cesarean delivery is required with placenta previa unless the placenta significantly changes position during gestation away from the cervical os before the time of delivery.

The term *placenta accreta* is often used to include the three subtypes of accreta vera, increta, and percreta. Placenta accreta vera is an abnormal adherence to the myometrium with an absent decidual line of separation. Placenta increta is abnormal implantation and growth of the placenta into the myometrium, and placenta percreta is growth of the placenta through the uterine wall with placental implantation onto surrounding tissue that might include bladder, bowel, ovaries, or other organs surrounding the uterus. Presence of accreta occurs in approximately 0.04% of pregnancies in developed countries; however, the rate is increasing and appears to affect from 0.17 to 0.34% of deliveries.[284,285] In a multi-institutional cohort study, the sensitivity for detecting placenta accreta using ultrasound or magnetic resonance imaging was 93% and 80% with specificities of 71% and 65%, respectively.[286] Rates of accreta are significantly affected by the presence of placenta previa and the number of prior hysterotomies. In patients with a known placenta previa, the rates of accreta are 3%, 11%, 40%, and more than 60% with zero, one, two, and three or more prior uterine incisions, respectively.[287] Unfortunately, the diagnosis of accreta is not certain until the time of hysterotomy, and in patients with significant risk factors, massive hemorrhage could occur, regardless of imaging study result.[92,283] If the diagnosis of placenta accreta or percreta is made before delivery, preoperative interventions such as bilateral common iliac artery balloon catheter insertion or selective embolization of uterine vessels near the time of delivery could be considered, but efficacy remains unclear.[288-290]

Vasa Previa

Vasa previa is a rare condition in which velamentous insertion of umbilical vessels occurs so that these fetal vessels traverse the fetal membranes and are positioned over the cervical os.[291,292] The incidence is between 0.04% and 0.02% of pregnancies and carries significant fetal morbidity and mortality if not diagnosed antenatally. In a study of 155 women, neonatal survival was 97% with antenatal diagnosis and only 44% without diagnosis before delivery.[293] If undiagnosed, vaginal bleeding may be noted at the time of membrane rupture and represents fetal blood loss rather than maternal. Previously undiagnosed vasa previa represents an obstetric emergency requiring immediate cesarean delivery, typically done under general anesthesia because of its rapidity. In cases in which the diagnosis is known antenatally, cesarean delivery is performed before labor. The optimal gestational age for delivery is not definitively established, but delivery by cesarean at approximately 36 weeks of gestation is suggested with consideration for administration of steroids for fetal lung maturity and consideration of maternal hospitalization between 28 and 32 weeks' gestation in the case of the need for urgent preterm delivery.[291,292]

Placental Abruption

Placental abruption is defined as partial or complete separation of the placenta from the uterine wall after 20 weeks' gestation but before delivery. The incidence is approximately 1% of pregnancies, and risk factors include advanced maternal age, chorioamnionitis, cocaine use, excessive alcohol use, hypertension, premature rupture of membranes, history of abruption, smoking, and trauma. Abruption often manifests with vaginal bleeding and uterine tenderness with examination. However, a significant volume of blood can be trapped behind the placenta and remain in the uterus. As for any situation with massive bleeding in pregnancy, coagulopathy resulting from massive blood loss can frequently occur. Patients with placental abruption (versus those without) were 54 times more likely to have a coagulopathy and 11 times more likely to have a fetal demise.[294] Appropriate laboratory panels should be obtained and preparation for massive transfusion and administration of additional coagulation factors initiated, taking into account the need for close collaboration with transfusion medicine or blood bank expertise (see later discussion of management of massive obstetric hemorrhage).

Uterine Rupture

Uterine rupture can be a life-threatening emergency for both the mother and the fetus. The occurrence rate for women undergoing a trial of labor after cesarean delivery ranges between 0.4% and 1% and includes a range of pathologic processes from cases of scar dehiscence to complete uterine wall rupture.[295] Other risk factors for uterine rupture include fetal malposition, instrumented delivery, macrosomia, excessive oxytocin administration, rapid delivery, trauma, and tumor. Typical clinical presentation includes fetal bradycardia, cessation of uterine contractions, abdominal pain, vaginal bleeding, and loss of station. A nonreassuring FHR tracing is the most reliable and sensitive clinical sign, and breakthrough pain may be present in only a minority of patients and unrelated to epidural use.[296-298] If trial of labor after cesarean delivery is the planned method of delivery, the American College of Gynecology recommends that an obstetrician, anesthesiologist, and nursing staff be immediately available to the laboring patient so that an emergent cesarean delivery and possible hemorrhage management can be started immediately if a rupture occurs.[299]

Uterine Atony

Postpartum uterine atony is the most common cause of severe postpartum hemorrhage. The associated hemorrhage is the leading cause of maternal death worldwide and is increasing in incidence.[226,300,301] Risk factors include chorioamnionitis; oxytocin use during labor, high parity, macrosomia, multiple births, prolonged labor, retained products of conception, and use of volatile anesthetics, magnesium sulfate, or terbutaline. After bimanual massage, oxytocin should be administered as the initial treatment and prophylactic drug for uterine atony. Specific dosing of oxytocin varies across institutions and countries.[302] Although the WHO recommends 20 international units of oxytocin administered in 1 L of crystalloid after uncomplicated cesarean delivery, less is likely needed in most situations.[303] There are advocates for more controlled modes of oxytocin administration including small doses immediately after delivery (3 international units administered over 30 seconds) and the use of an infusion pump. Although a dilute oxytocin solution administered over a long time has minimal hemodynamic effects and is typically well tolerated, larger doses and bolus infusion can result in significant hypotension, tachycardia, nausea, and headache. If oxytocin is not sufficient in controlling postpartum hemorrhage, methylergonovine 0.2 mg intramuscularly, carboprost (which is prostaglandin $F_2\alpha$ [$PGF_2\alpha$]) 0.25 mg intramuscularly, or misoprostol (which is a prostaglandin E_1 analog [PGE_1]) 600 to 800 µg orally, sublingually, vaginally, or rectally should be considered. These drugs can have a variety of side effects.[304] Side effects of methylergonovine, an ergot derivative, include nausea, hypertension (systemic and pulmonary), and coronary artery spasm, and it is relatively contraindicated in patients with preeclampsia and those with cardiac disease. $PGF_2\alpha$ is associated with pulmonary hypertension, bronchospasm, desaturation, nausea, and tachycardia, and is contraindicated in patients with asthma. PGE_1 does not have significant cardiovascular effects but may result in mild hyperthermia. If postpartum hemorrhage is not controlled with drugs, invasive and surgical techniques described in the following section should be considered.

Management of Massive Obstetric Hemorrhage

Successful management of a massive obstetric hemorrhage requires excellent communication and coordination of all perioperative disciplines, including anesthesiologists, obstetricians, labor and operating room nurses, neonatologists, interventional radiologists, gynecologic surgeons, and blood bank staff. Early diagnosis of hemorrhage and timely intervention are key to minimizing patient morbidity and mortality. Although few studies regarding hemorrhage in obstetrics exist, many studies have been published from the military and trauma hospitals regarding transfusion ratios and transfusion triggers. The development of a massive transfusion protocol has been beneficial in massive obstetric hemorrhage. Specific ratios of fresh frozen plasma (FFP) to packed red blood cells (PRBCs) for management of massive obstetric hemorrhage originate from nonobstetric settings and have been questioned by experts in obstetric hemorrhage in recent years.[305,306] Although frequent laboratory studies with use of point-of-care testing if available is optimal, transfusion of blood products should initially be guided by the clinical situation and patient assessment rather than waiting for laboratory values to return. Cryoprecipitate or fibrinogen concentrate should be considered if decreased fibrinogen is present or likely. TEG and rotational thromboelastometry (ROTEM) can be used as tools for both diagnosis and treatment of hemorrhage-related coagulopathy. Recombinant activated factor VII is not universally recommended as multiple adverse events have been reported to the FDA with the off-label use of treating massive hemorrhage with factor VIIa.[307-309]

Tranexamic acid is an antifibrinolytic that is used in trauma, cardiac surgery, and multiple surgical populations to decrease blood loss. It is a lysine analogue that binds to receptors on plasminogen and plasmin, which results in inhibition of plasmin-mediated fibrin degradation. A large randomized, double-blind, placebo-controlled trial randomized 20,060 women to receive either tranexamic acid or placebo at the time postpartum hemorrhage was diagnosed. The authors found a reduction in death due to bleeding in women with postpartum hemorrhage if given within 3 hours (RR 0.69; 95% CI, 0.52-0.91; $P = .008$).[310] There was no difference between the two groups in terms of thromboembolic event or other side effects. In its most recent practice bulletin on postpartum hemorrhage, ACOG recommends that tranexamic acid should be considered when initial medical therapy for postpartum hemorrhage fails.[311] Tranexamic acid can cross the placenta and into breastmilk and it is recommended to wait until the cord is clamped to administer the drug. Evidence about the effectiveness of *prophylactic* administration of tranexamic acid to prevent postpartum hemorrhage is still lacking. A multicenter, double-blind, randomized, controlled trial randomized 4079 women to receive prophylactic tranexamic acid or placebo, in addition to oxytocin, after a vaginal delivery and found the use of tranexamic acid did not reduce risk of postpartum hemorrhage compared to placebo.[312,313] Tranexamic acid is contraindicated in patients with active venous thromboembolism, significant renal disease, and subarachnoid hemorrhage.

Cell salvage has been used successfully in numerous published cases of obstetric hemorrhage despite the theoretic concern of amniotic fluid embolism.[314,315] The use of a salvage device with a leukocyte reduction filter has been demonstrated to remove tissue factor, α-fetoprotein, fetal squamous cells, bacteria, and other undesirable contaminants.[316,317] Cell salvage can be especially helpful if the supply of autologous blood is limited for a patient or in the event a patient refuses blood products. Even when these scenarios do not exist, cell salvage has been shown to be cost-effective in cases of massive obstetric hemorrhage.[317] In parturients who are Rh negative, anti-D immunoglobulin should be used as soon as possible in coordination with Kleihauer-Betke testing to prevent alloimmunization because variable amounts of fetal RBCs will be transfused to the mother with use of cell salvage.

When standard resuscitation methods are not adequate to control the obstetric hemorrhage, the peripartum obstetric team should consider use of invasive options, including uterine balloon tamponade, compression sutures, ligation of uterine vessels, and use of interventional radiology for arterial embolization if the patient is stable for transport. Based on a systematic review of the literature, no single invasive option is significantly better than another, and all have success rates of approximately 85% to 90%.[318] If these options fail or are not feasible, a hysterectomy should be performed.

AMNIOTIC FLUID EMBOLISM

The incidence of amniotic fluid embolism (AFE) is difficult to estimate because the diagnosis is difficult to establish. The incidence varies between 1.7 and 7.7 per 100,000 deliveries.[319-321] Signs and symptoms of AFE include hypotension, respiratory distress, hypoxia, disseminated intravascular coagulation (DIC), altered mental status, and hemodynamic collapse. This constellation of clinical features must be differentiated from other more common conditions that mimic AFE (i.e., venous air embolism, pulmonary embolism, cardiac dysfunction, massive hemorrhage, and pulmonary aspiration). The mechanism of AFE remains unclear, but it is no longer believed to be embolic, but rather an anaphylactoid reaction.[319,322] Previously, AFE was diagnosed based on the presence of fetal squamous cells in the maternal pulmonary circulation at autopsy, but the presence of these cells is frequently noted in the pulmonary circulation of healthy pregnant women around the time of labor and delivery. Consequently, determining the occurrence of an AFE is a clinical diagnosis of exclusion and no diagnostic laboratory test for AFE currently exists, even postmortem. Early recognition and aggressive resuscitation may improve outcomes in both the mother and fetus. The priorities of resuscitation include oxygenation, hemodynamic support, and correction of coagulopathy.[323]

SHOULDER DYSTOCIA

Shoulder dystocia occurs when after the delivery of the head, the shoulders cannot be delivered secondary to impaction on the maternal pelvis. This is an obstetric emergency. It is associated with prolonged gestation, labor induction, obesity, high fetal weight, prolonged dilation from 8 to 10 cm, and epidural analgesia.[324,325] Prolonged gestation and slow difficult delivery make epidural analgesia more desirable, so the association between epidural analgesia and shoulder dystocia is not causal. However, epidural analgesia provides superior conditions for rescue of the infant in the case of shoulder dystocia. Recommended procedures for the management of shoulder dystocia include the McRoberts maneuver, in which the mother's legs are flexed and pushed tightly to her abdomen with application of suprapubic pressure.[326] The muscle relaxation and pain relief offered by epidural analgesia facilitate this process. However, the Gaskin maneuver requires placing the mother on her hands and knees, which may not be possible to sustain with the use of higher dose epidural local anesthetic because of inadequate motor strength. If these maneuvers are unsuccessful, pushing the fetus back into the pelvis and emergent cesarean delivery may be required. Deliveries with shoulder dystocia have an increased risk for postpartum hemorrhage and fourth-degree lacerations.[327]

OTHER OBSTETRIC EMERGENCIES

Certain urgent situations may occur around the time of labor and delivery that require tailored anesthetic care to optimize both the maternal and fetal outcome. Cord prolapse through the cervical os can result in abrupt fetal bradycardia. Rates of umbilical cord prolapse range between 0.1% and 0.6%.[328] The risk is significantly increased with the presence of transverse lie, breech presentation, multiple gestations, and an abnormally long umbilical cord. In addition, cord prolapse may occur around the time the membranes are ruptured if an abnormal fetal presentation is present or the mother has polyhydramnios. Diagnosis is confirmed with visualization or palpation of the cord in the vaginal canal below the presenting fetal part. Intervention typically consists of elevating the compressing fetal part back into the pelvis off of the cord until an urgent cesarean delivery can be performed. Use of an in situ epidural catheter or spinal technique can be considered as long as the FHR tracing is reassuring, but general anesthesia is frequently used in the event of fetal compromise.

Uterine inversion occurs in approximately 0.04% of deliveries[329] and is usually associated with hypotension, pain, and severe postpartum hemorrhage. Risk factors include excessive cord traction before placental separation, uterine atony, location of the placenta at the fundus, and the presence of placenta accreta. Treatment goals include relaxation of the uterus to aid replacement back through the cervix, maternal fluid resuscitation, and increased uterine tone after replacement to reduce postpartum hemorrhage. Initially, all uterotonic drugs should be immediately discontinued. Uterine relaxation can be quickly and reliably achieved using either intravenous nitroglycerin or volatile anesthetics.[330-332] The mother's hemodynamic condition may guide the choice of therapy. If the initial uterine intervention and replacement is not successful with nitroglycerin because of lack of relaxation, maternal pain, hemodynamic instability, or other logistics, transfer to the operating room should occur. A rapid sequence intubation with standard obstetric precautions followed by volatile anesthetic administration will allow needed uterine relaxation, pain control, and procedural conditions for uterine replacement. Only on rare occasions are vaginal maneuvers unsuccessful and laparotomy required. After uterine replacement, the uterine cavity should be explored for perforation, laceration, or retained products. After the uterus has been replaced, uterotonic drugs can be started.

Lacerations of the vagina, cervix, and perineum are the most common injuries associated with vaginal birth. Significant bleeding can be concealed in hematomas, and maternal hypotension and tachycardia may be the first signs of the injury. Retroperitoneal hematomas are rare but can represent substantial life-threatening blood loss that requires exploratory surgery. Anesthetic management to allow surgical repair or exploration depends on the hemodynamic state of the mother and can include use of local anesthetic at the site, neuraxial blockade, or—in severe hemodynamic compromise—use of general anesthesia. Equally important is the hemodynamic assessment and initiation of resuscitation efforts for the mother. Even small unrecognized lacerations can result in significant blood loss.

ADVANCED CARDIAC LIFE SUPPORT IN PREGNANCY

Cardiac arrest in pregnancy involves the simultaneous care of two patients, the mother and fetus. The protocol for advanced cardiac life support (ACLS) in pregnancy is similar to that recommended for other adult cardiac arrest situations; however, compression of the maternal great vessels by the pregnant uterus greatly impedes the success of external cardiac massage. First responders should utilize strategies to oxygenate the patient while laryngoscopy should be performed by providers with advanced airway management experience. Although pregnant women are at increased risk of aspiration, oxygenation and ventilation should remain primary objectives and take precedence over aspiration prevention strategies. Intravenous access should be placed above the diaphragm and the patient should be supine with manual displacement of the uterus. If there is no return of spontaneous circulation after 4 minutes of resuscitative efforts, consider performing immediate cesarean delivery at the site of cardiac arrest with an aim for delivery within 5 minutes of maternal cardiac arrest.[19] Although potentially beneficial for the fetus if viable, hysterotomy and delivery improves ACLS effectiveness.[333] If the maternal cardiac arrest may have been caused by local anesthetic toxicity, lipid rescue should be initiated.[334]

BOX 62.3 **Anesthetic Considerations for Nonobstetric Surgery in the Pregnant Patient**

- Postpone elective surgeries until after delivery.
- Regional anesthesia should be utilized when possible.
- Consider aspiration prophylaxis.
- Left uterine displacement to relieve aortocaval compression after 20 weeks' gestational age
- Consider intraoperative fetal monitoring.
- Regional anesthesia
  - Reduced local anesthetic requirements in pregnancy
- General anesthesia
  - Maximize preoxygenation
  - Rapid sequence induction
  - Avoid hypoxia and hypotension
  - Goal $ETCO_2$ 28-32 mm Hg. Avoid hyperventilation as hypocarbia can decrease placental blood flow secondary to uterine vasoconstriction.
  - Extubate when awake
- Fetal heart rate and uterine tone should be monitored postoperatively.
- Provide appropriate postoperative analgesia.

$ETCO_2$, End-tidal carbon dioxide.

Nonobstetric Surgery During Pregnancy

PERIOPERATIVE CONSIDERATIONS

Although elective surgery is not performed during pregnancy, ACOG recommends that pregnant women should not be denied a medically indicated procedure. Between 0.75% and 2% of pregnant women will require nonobstetric surgery. The most common indications for surgery include acute appendicitis and cholecystitis, maternal trauma, and cancer.[335] Box 62.3 provides a summary of the anesthetic considerations for the pregnant patient.

ANESTHETIC TOXICITY

All general anesthetic drugs cross the placenta; however, when standard dosing is used, current anesthetic drugs have not been shown to be teratogenic in humans. Although no clear evidence exists for toxicity of specific anesthetic drugs in humans, data in rodents and primates suggest that exposure to general anesthetic drugs, including volatile anesthetics, propofol, and ketamine, induce inappropriate neuronal apoptosis that is associated with long-lasting behavioral abnormalities.[336-338] These preclinical results are concerning, but whether these drugs cause toxicity in humans is not known. The critical period of rapid synaptic development is extended in humans from the prenatal period through 2 years of postnatal life.[339] Analyses of existing human data have found conflicting evidence and the results of these studies are difficult to interpret because the reason for anesthesia cannot be separated from the impact of anesthesia (see Chapter 77). Studies reveal no association between surgery and major birth defects, but there may be a small increase in the risk for preterm delivery or miscarriage, especially with abdominal surgeries.[340-342] In general, the second trimester is preferred for surgical intervention because this is a period after organogenesis but the risk for preterm labor is less than in the third trimester. In 2016, the FDA issued a warning that repeated or lengthy use of general anesthetic drugs during surgery in children less than 3 years of age or in pregnant women in the third trimester may affect the development of children's brains. There is concern that the warning could delay necessary surgeries or procedures and result in adverse outcomes for these patients especially as there is lack of data regarding adverse consequences of human fetal exposure to anesthesia.[343]

Monitoring for contractions is recommended, and in some situations suppression with tocolysis may be appropriate. Because the long-term impact of general anesthesia on the fetus is unknown, regional anesthesia is favored when possible for the surgical procedure but should not be undertaken unless both the anesthesiologist and surgeon are experienced in using the technique for a given procedure, and the mother is comfortable being awake.

PERIOPERATIVE FETAL HEART RATE MONITORING

Fetal well-being should be monitored in the perioperative period. ACOG recommends in a previable pregnancy, fetal heart rate measurement by Doppler before and after the procedure. In a viable fetus, minimum recommendations include electronic FHR monitoring and contraction monitoring before and after the procedure. Continuous intraoperative fetal monitoring is often used and FHR variability is a reliable sign of fetal well-being. Under general anesthesia, loss of FHR variability is expected while fetal bradycardia is more concerning and can be affected by hypothermia, maternal acidosis, or the maternal administration of drugs such as particular β-blockers that can cross the placenta and reduce FHR. The type of fetal monitoring is a decision that should be made in consultation with an obstetrician and should be based on an assessment of the individual patient and gestational age, procedure, and facilities available.[344]

ANESTHETIC MANAGEMENT

To minimize fetal exposure to anesthesia, regional anesthesia is preferred when possible to general anesthesia for nonobstetric surgery in pregnancy. Preoxygenation followed by a rapid sequence induction and endotracheal tube placement are recommended for general anesthesia. Starting in the second trimester, the increase in peripheral blood flow induced by pregnancy results in airway edema and friability. Pregnant women are at increased risk of difficult intubation and advanced airway equipment should be readily available prior to intubation. Equally important to anesthetic technique is avoidance of decreased uterine blood flow and oxygen delivery to the fetus as uterine blood flow is not autoregulated. Considerations similar to those discussed in the section on anesthesia for cesarean delivery should be undertaken for any nonobstetric surgery during pregnancy. The anesthetic plan should optimize both the maternal and fetal condition. Perioperative team planning should include consultation with an obstetrician regarding plans for unexpected events, including need for emergent cesarean delivery.

POSTOPERATIVE PAIN CONTROL

Maternal pain control after nonobstetric surgery is important to maternal well-being and could theoretically decrease the risk of preterm labor, especially after abdominal surgery. Multimodal analgesia is recommended. When intraoperative regional anesthesia with an epidural is used, it often can be continued for postoperative analgesia. Postoperative systemic opioids, including those used in patient-controlled analgesia, cross the placenta and may reduce FHR variability. If the fetus is born prematurely shortly after exposure to maternal systemic opioids, respiratory support may be necessary. Nonsteroidal antiinflammatory drugs, though useful adjuvant analgesics outside of pregnancy, are typically avoided in pregnancy. They are associated with an increased risk for miscarriage and fetal malformation when used early in pregnancy and premature closure of the ductus arteriosus and oligohydramnios when used after 30 weeks' gestation.[345] Acetaminophen, oral or intravenous, is generally accepted as safe in pregnancy.

After surgery, both the FHR and uterine activity should be monitored. Preterm labor can be managed with appropriate tocolytic drugs. Distracting pain and postoperative pain relief medications may make it difficult for the patient to note early contractions and patient perception should not be considered a substitute for standard fetal and contraction monitoring postoperatively. In addition, thromboprophylaxis should be instituted unless surgically contraindicated.

SPECIFIC SURGICAL TECHNIQUES

Laparoscopy

Surgery for appendicitis and cholecystitis are common in pregnancy. These surgeries are typically performed with a laparoscopic technique outside of pregnancy and are increasingly more common in pregnancy because of reduced morbidity for the mother and potentially a decreased incidence of preterm labor as a result of reduced manipulation of the uterus.[346] A recent meta-analysis of 20 studies involving 6210 pregnant women found open appendectomy may have a slightly less frequent rate of fetal mortality and prolonged gestation compared with laparoscopic appendectomy, although hospital length of stay and overall complications were more frequent.[347] However, a study of over 2 million pregnancies in Sweden comparing laparoscopies and laparotomies found no difference in fetal outcome between the two techniques.[348] Left uterine displacement should be maintained after the second trimester to facilitate uterine perfusion. With increased abdominal pressure from insufflation, maternal cardiac output and uteroplacental perfusion may decrease. Thus the smallest possible intraabdominal pressure should be used.

According to the guidelines issued by the Society of American Gastrointestinal Endoscopic Surgeons regarding laparoscopic surgery during pregnancy,[349] whenever possible, surgery should be deferred to the second trimester and indications for the use of laparoscopic techniques are the same as in nonpregnant patients. Normocapnia should be maintained, and fetal and uterine status should be monitored. During laparoscopic surgery, gradients between end-tidal CO_2 and arterial CO_2 are typically less than 3 mm Hg, and although some anesthesia providers feel that arterial blood gas monitoring is not needed unless otherwise indicated,[350] many may choose to follow $PaCO_2$ to be sure to avoid hypercapnia or hypocapnia. An open technique is preferred to enter the abdomen. Aortocaval compression should be avoided. Finally, low pneumoperitoneal pressure (15 mm Hg) should be used. A systematic review of laparoscopic surgery for appendicitis during pregnancy noted that trimester timing did not influence the complication rate, the need for conversion to open was less than 1%, and there was a lower rate of preterm delivery with laparoscopic in contrast to the open approach.[351]

Trauma

The most common nonobstetric cause of maternal death in the United States is trauma. Initial primary and secondary survey should be directed toward maternal well-being, with consideration of the physiologic changes induced by pregnancy. Gestational age is an important variable in trauma evaluation. During the first trimester, the fetus is protected by the bony pelvis and damage is unlikely in the absence of severe hypoperfusion. However, as pregnancy progresses, the uterus is not only exposed but also causes pressure on the maternal inferior vena cava and aorta, potentially compromising perfusion and resuscitation. After 20 weeks' gestation, left uterine displacement should be implemented as the initial step. Blunt trauma carries a risk for intrauterine fetal demise, fetal injury, placental abruption, and uterine rupture. These dangers should be evaluated with fetal heart monitoring, ultrasonography, computed tomography, or exploratory laparotomy when indicated.[352] The consequences for ACLS are discussed earlier in the chapter.

Cardiac Surgery

The hemodynamic changes of pregnancy can exacerbate the symptoms of some preexisting heart diseases. The increase in intravascular volume and cardiac output can result in heart failure and arrhythmias in patients with moderate to severe mitral or aortic valvular stenosis. These patients may require a cardiac intervention during pregnancy. Percutaneous balloon valvuloplasty may obviate open cardiac intervention in pregnancy and has been associated with reduced fetal and neonatal mortality.[353,354] Cardiopulmonary bypass increases risk to the fetus as a result of nonpulsatile perfusion, low perfusion pressures, emboli to the uteroplacental unit, and maternal release of catecholamines.[355] Higher pump flows (>2.5 L/min/m^2) and perfusion pressures (>70 mm Hg) are recommended to support uteroplacental blood flow.[356,357] Normothermic bypass and pulsatile flow may better preserve uteroplacental perfusion and improve fetal survival. Hypothermic (versus normothermic) bypass has been associated with greater fetal loss. Hypocapnia should be avoided because it causes uteroplacental vasoconstriction and decreased oxygen delivery to the fetus. Likewise, hypercapnia causes fetal acidosis.

Neurosurgery

Intracranial hemorrhage secondary to aneurysm rupture or arteriovenous malformation can be a neurosurgical emergency made more complex by pregnancy. The risk for intracranial hemorrhage is increased by hypertensive diseases of pregnancy. In patients who are not pregnant, usual anesthetic treatment might include controlled hypotension, hyperventilation, and osmotic diuresis. Such techniques need to be conducted with particular care in pregnancy. Reduction of mean arterial pressure below 70 mm Hg may significantly reduce uteroplacental perfusion and use of fetal monitoring should be considered as a guide to fetal well-being. Extreme hyperventilation can cause uterine artery vasoconstriction and reduce uterine perfusion. Hyperventilation also shifts the maternal oxyhemoglobin dissociation curve to the left, which decreases oxygen delivery to the fetus. Osmotic diuresis, used to reduce brain edema, could theoretically decrease amniotic fluid volume and cause negative fluid shifts in the fetus. In animal studies, mannitol may accumulate in the fetus, leading to hyperosmolarity, reduced renal blood flow, and increased plasma sodium concentration.[358] A case report of a single dose of mannitol used for awake craniotomy in a pregnant patient revealed a reduction of intrauterine volume with subsequent volume recovery after 48 hours and no fetal adverse effects.[359] Loop diuretics are an alternative to osmotic diuretics but should be used with care and monitoring of amniotic fluid volume.

Acknowledgment

The editors and the publisher would like to thank Drs. Pamela Flood and Mark D. Rollins for contributing a chapter on this topic in the prior edition of this book. It has served as the foundation for the current chapter.

Anesthesia for Fetal Surgery and Other Fetal Therapies

MARLA B. FERSCHL and MARK D. ROLLINS

KEY POINTS

- Most fetal anomalies are not appropriate for in utero treatment. A condition appropriate for fetal treatment should cause ongoing irreversible harm to the fetus that is mitigable by early treatment before the fetus can tolerate ex utero neonatal intervention.
- A multidisciplinary approach with open communication is essential to the success of each fetal intervention.
- Maternal safety and the principle of "do no harm" should be foremost in determining the most appropriate therapeutic option. A thorough maternal and fetal evaluation and frank discussion of risks and benefits by all team members with the mother is required to determine an appropriate care plan.
- Although open fetal surgery typically requires general anesthesia, most minimally invasive percutaneous techniques can be performed using local anesthesia infiltration or neuraxial anesthesia techniques.
- Randomized controlled clinical trials show improved outcomes with fetoscopic laser photocoagulation of placental vessels to treat twin-to-twin transfusion syndrome and intrauterine open fetal surgery to treat myelomeningocele.
- In addition to anesthetic considerations associated with nonobstetric surgery during pregnancy, fetal surgery requires planning for fetal anesthesia and analgesia, fetal monitoring, uterine relaxation, preparation for emergent events (e.g., fetal bradycardia, maternal hemorrhage), and postoperative tocolysis.
- Membrane separation, preterm premature rupture of membranes, and preterm labor remain the most common causes of morbidity and suboptimal outcome with fetal surgical interventions.
- Further research into optimal anesthetic techniques for various fetal interventions is essential to improve patient outcomes and advance the field of fetal surgery.

Only recently have medical professionals focused on the human fetus as a patient who is able to undergo surgery or medical intervention. This development has been primarily driven by systematic improvements in prenatal diagnosis, imaging technology, and surgical equipment. Although many fetal surgical procedures are available only at highly specialized institutions, some prenatal interventions are considered conventional therapy and have become more widespread. This chapter reviews the unique pathophysiological processes of various fetal and placental conditions amenable to intervention, current outcome data, specific procedural considerations, and perioperative anesthesia management.

Most fetal abnormalities are not appropriate for antenatal intervention and are more amenable to treatment after delivery. However, some anatomic malformations may result in irreversible end-organ damage and would benefit from intervention before birth. This has led to the theory that surgical or procedural correction in utero could allow normal fetal development and might mitigate much of the detrimental pathologic processes observed.[1] Other defects, such as congenital airway obstruction, can be managed intrapartum by keeping the uteroplacental unit intact while the defect is repaired or airway secured, without the urgency that would be associated with attempting similar procedures immediately after birth.

Prerequisite guidelines for performing fetal surgery were initially developed in 1982 at a multidisciplinary meeting with participants from 13 medical centers representing five countries.[2] Over time these criteria have evolved and include: (1) the fetal lesion is accurately diagnosed; (2) the progression and severity of the anomaly is predictable and well understood; (3) other severe associated anomalies that would contraindicate fetal intervention are excluded; (4) the fetal abnormality would lead to fetal demise, irreversible organ damage, or severe postnatal morbidity if left untreated before birth, and intervening before birth would benefit the neonatal outcome; (5) the maternal risk is acceptably low; (6) animal models have demonstrated feasibility of the surgical technique; (7) fetal interventions are performed at specialized multidisciplinary institutions using protocols approved by the center's ethics committees with maternal informed consent; and (8) the patient has access to highly specialized multidisciplinary care including bioethical and psychological counseling.[1-3]

TABLE 63.1 Fetal Conditions Currently Considered for Intervention

Fetal Condition	Therapy Rational	Type	Intervention
Fetal anemia or thrombocytopenia	Prevention of heart failure and fetal hydrops	FIGS-IT	Intrauterine transfusion
Aortic stenosis, intact atrial septum, or pulmonary atresia	Prevention of fetal hydrops, myocardial dysfunction, and hypoplastic left (and right) heart	FIGS-IT	Percutaneous fetal valvuloplasty or septoplasty
Lower urinary tract obstruction	Bladder decompression with reduction in renal dysfunction, pulmonary hypoplasia, oligohydramnios, and limb malformation	FIGS-IT or fetoscopy	Percutaneous vesicoamniotic shunting or fetoscopic posterior urethral valve laser ablation
Twin reversed arterial perfusion	Prevention of high-output cardiac failure in the normal twin by stopping flow to acardiac twin	FIGS-IT or fetoscopy	Image-guided radiofrequency ablation or fetoscopic coagulation of acardiac twin umbilical cord. Percutaneous coiling or ligation of umbilical cord is also used.
Twin-twin transfusion syndrome	Reduction of twin-twin blood flow and prevention of cardiac failure	Fetoscopy	Fetoscopic laser photocoagulation of placental vessels and amnioreduction
Amniotic band syndrome	Prevention of limb loss	Fetoscopy	Fetoscopic band ablation
Congenital diaphragmatic hernia	Prevention of pulmonary hypoplasia	Fetoscopy	Fetoscopic tracheal occlusion
Myelomeningocele	Reduction in hydrocephalus and hindbrain herniation, with reduced spinal cord damage and improved neurologic function	Open or Fetoscopy	Closure of fetal defect through hysterotomy
Sacrococcygeal teratoma	Prevention of high-output cardiac failure, hydrops, and polyhydramnios	FIGS-IT or open	Ablation of tumor vasculature or open fetal tumor debulking
Congenital cystic adenomatoid malformation	Reversal of pulmonary hypoplasia and cardiac failure	FIGS-IT or open	Thoracoamniotic shunting or open surgical resection
Fetal airway compression	Secured open airway and/or circulatory support to prevent respiratory compromise at birth	Open intrapartum	Ex-utero intrapartum therapy (EXIT) that allows fetal stabilization while on uteroplacental circulation

FIGS-IT, Fetal image-guided surgery for intervention or therapy.
Modified from Partridge EA, Flake AW. Maternal-fetal surgery for structural malformations. *Best Pract Res Clin Obstet Gynaecol*. 2012;26:669–682; and Hoagland MA, Chatterjee D. Anesthesia for fetal surgery. *Paediatr Aneasth*. 2017;27:346–357.

All interventions should be preceded by a thorough multidisciplinary team deliberation of the clinical case. Discussions should focus on a comprehensive risk–benefit analysis, and the family should be provided appropriate counseling that includes options for elective termination or continuation of the pregnancy without fetal therapy. Potential risks to the mother should be part of the informed consent, and a detailed maternal preoperative evaluation should be performed to ensure maternal risks are minimal.[4]

The advancement of fetal surgery has benefited from a multidisciplinary approach and establishment of the International Fetal Medicine and Surgery Society to disseminate techniques and outcome data through an international registry.[5] Medical centers offering fetal treatment rely on surgeons and anesthesiologists devoted to the care and counseling of these complex maternal and fetal patients, as well as the expertise of radiologists, perinatologists, geneticists, neonatologists, psychologists, social workers, and numerous support staff. A bioethics committee derived from both the American College of Obstetricians and Gynecologists and the American Academy of Pediatrics has provided guidelines for fetal treatment centers and recommends a comprehensive informed consent and counseling process, maternal-fetal research oversight, use of a multidisciplinary approach, and participation in a collaborative data-sharing fetal therapy network.[6]

Fetal surgery is broadly categorized into three types of interventions: minimally invasive procedures, open procedures, and intrapartum procedures. A summary of conditions considered for fetal intervention with corresponding rationale and recommended treatment is shown in Table 63.1.

Minimally invasive fetal procedures include (1) percutaneous interventions guided by ultrasound, also known as fetal image-guided surgery for intervention or therapy, and (2) fetal endoscopic surgery using small endoscopic instruments inserted percutaneously guided by direct fetoscopic camera view and simultaneous real-time ultrasound imaging. With these minimally invasive approaches, the risks for preterm labor and delivery are reduced compared with those in open procedures that include a hysterotomy. Unlike in open fetal procedures, the mother can safely undergo a vaginal delivery for this and future pregnancies. However, the risk for preterm premature rupture of membrane (PROM) remains significant.[7]

Open fetal procedures involve a maternal laparotomy, a hysterotomy, and the need for intraoperative uterine relaxation. These procedures incur significantly more risk to both the fetus and mother than minimally invasive procedures. These increased risks include preterm PROM, oligohydramnios, preterm labor and delivery, uterine rupture, and fetal mortality.[8,9] Additional maternal and fetal risks include not only the anesthetic risks noted for nonobstetric surgery during pregnancy (see also Chapter 62), but also pulmonary edema, hemorrhage, membrane separation, and chorioamnionitis.[4,8] Cesarean delivery is required after an open fetal procedure and for all future pregnancies owing to the increased risk for uterine dehiscence or rupture at the site of the hysterotomy.

For fetuses with known airway compromise or obstruction, an ex utero intrapartum therapy (EXIT) procedure[10] allows continued fetal support by the intact uteroplacental unit (placental bypass) while the fetal airway is secured or other procedures completed without the concern for postnatal respiratory compromise, hypoxia, and asphyxia. The EXIT procedure has become a widely practiced fetal intervention for a growing list of indications. Congenital high airway obstruction due to laryngeal stenosis, laryngeal web, cystic hygroma, lymphangioma, or cervical teratoma is the most common anatomical indication for an EXIT procedure.[11] Congenital pulmonary lesions and sacral teratomas have also been resected during the EXIT procedure, with resulting normal umbilical cord carbon dioxide and pH values at birth, even when surgical time has exceeded 2.5 hours.[12] Extracorporeal membrane oxygenation (ECMO) can be initiated during an EXIT procedure for a fetus with significant cardiopulmonary disease.[13]

Much of the success of fetal therapy in the past three decades can be attributed to advances in both ultrasonography and magnetic resonance imaging (MRI), which have substantially improved the accuracy of prenatal diagnosis and expanded our understanding of the pathophysiologic factors of various untreated fetal abnormalities. Significant advancements in ultrasonographic transducer hardware and digital signal processing have resulted in better image resolution with more accurate differentiation of abnormal fetal anatomy, wider fields of view, and improvement in the dynamic range for both near-field and far-field signal-to-noise ratio. Use of this improved ultrasonographic imaging as a real-time guide has enabled practitioners to develop and perform various diagnostic tests and fetal therapies more precisely and safely. Examples of fetal ultrasound-guided diagnostic procedures include first-trimester chorionic villus sampling, embryofetoscopy, amniocentesis, umbilical cord sampling, and fetal biopsies.[14] These diagnostic advances allow more accurate prenatal consultation, the ability to intervene at an earlier gestational age (GA), and usually enough time to change the location of antepartum care and the delivery plan if needed. Live ultrasound is typically used to guide all minimally invasive fetal procedures and is also critical to initial portions of open fetal procedures and fetal monitoring.

MRI has undergone technologic improvements that have reduced image acquisition time, decreased motion artifacts, and enhanced image resolution to a point at which fetal MRI is frequently used in conjunction with ultrasound to better detect and evaluate anatomic pathologic processes. Fetal MRI can aid in diagnosis as a complementary technique to ultrasound as it provides a larger field of view that is not obscured by fetal bone artifact, but it is expensive and not available in all centers.[15,16]

In addition to advances in imaging technology, decades of procedural innovations and research have provided the basis for the in utero fetal interventions used clinically today. Initial pioneers in the field of fetal therapy include Sir (Albert) William Liley. In the early 1960s, Liley was the first to successfully treat erythroblastosis fetalis with an intraperitoneal blood transfusion that allowed the transfused red cells to be absorbed into the fetal circulation through the subdiaphragmatic lymphatics and thoracic duct.[17,18] Unfortunately, initial attempts to perform fetal blood transfusion through direct cannulation of the umbilical vessels were unsuccessful until 1981, when a reliable technique that employed fetoscopy was described.[19,20] With improved imaging resolution, the standard technique quickly became direct needle access of the umbilical vessels using ultrasound guidance. In the early 1970s, Liggins administered corticosteroids to the fetus via the maternal circulation to increase surfactant production in preterm fetuses at risk for respiratory distress syndrome.[21] Fetal surgery began in the early 1980s after rigorous research efforts and technical advancements in sheep[22-24] and monkey models.[25] Harrison and colleagues performed the first successful human fetal surgery by creating a vesicostomy in a fetus with a congenital lower urinary tract obstruction (LUTO) resulting in bilateral hydronephrosis.[26] Working with Harrison in the early 1980s, Rosen refined fetal anesthetic techniques in monkeys to improve intraoperative uterine relaxation[25] and clinical outcome before employing them for the first human fetal surgeries. Since the early 1980s, great advances have been made in the development of minimally invasive percutaneous surgical techniques, fetoscopy, and procedural aspects of open fetal surgery with hysterotomy. Fetal therapy has also advanced in its outcome evaluation from published case reports and series to prospective randomized controlled trials.

Fetal surgery is a reasonable therapeutic intervention for certain correctable fetal anomalies with predictable, life-threatening, or serious developmental consequences. With all types of fetal intervention, meticulous planning and a multidisciplinary team approach are critical to a successful outcome. The following sections provide a review and summary of the congenital lesion, outcome data, procedural considerations, and perioperative anesthesia considerations for the various conditions currently amenable to fetal intervention.

Indications, Procedures, and Outcomes

ANEMIA AND INTRAUTERINE TRANSFUSION

The incidence of fetal anemia secondary to rhesus D (RhD) sensitization has decreased since the introduction of RhD immunoglobulin prophylaxis in the late 1960s, to rates of approximately 1 in 1000 pregnancies.[18] However, other red blood cell (RBC) antigens, parvovirus B19 infection, maternal-fetal hemorrhage, and homozygous thalassemia also cause fetal anemia and combine to reach a rate of approximately 6 cases in 1000 live births.[18,27] Although spectral analysis examining bilirubin levels in serial amniotic fluid samples was originally used to detect fetal anemia and determine the timing of therapy, most treatment centers currently rely on noninvasive Doppler studies of the middle cerebral artery (MCA).[27] An increased peak MCA blood flow velocity more than 1.5 multiples of the median is an accurate threshold in detecting moderate-to-severe fetal anemia requiring intervention.[28] The value of this peak velocity threshold may be increased with each serial

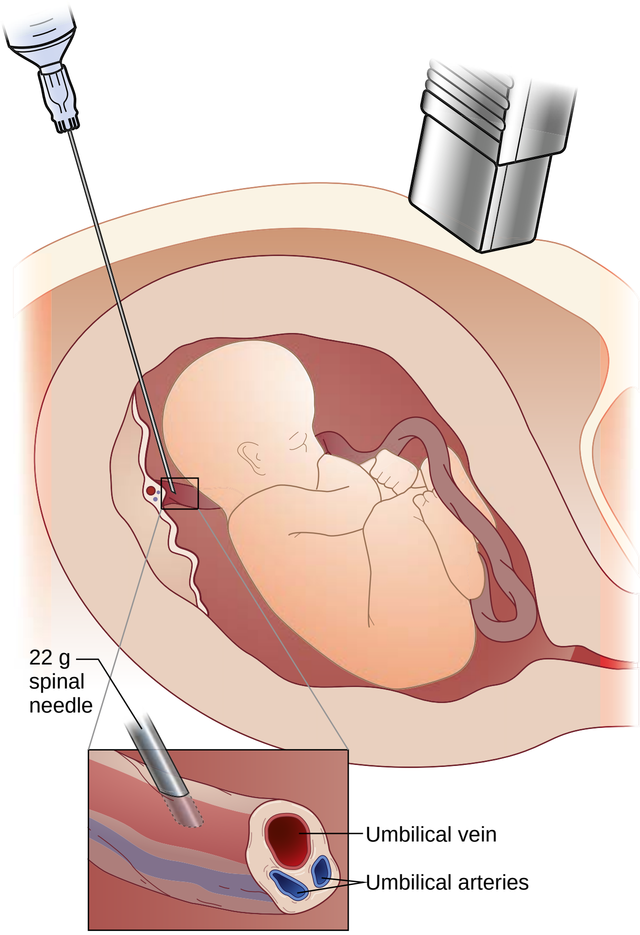

Fig. 63.1 Diagram of cordocentesis procedure used in intrauterine transfusion. Inset window shows tip of 22-gauge spinal needle entering the umbilical vein. (Redrawn from Ralston SJ, Craigo SD. Ultrasound-guided procedures for prenatal diagnosis and therapy. *Obstet Gynecol Clin North Am*. 2004;31:101–123.)

transfusion treatment to decrease the false positive rate. Fetal blood sampling from the umbilical vein just before starting the intrauterine transfusion (IUT) is the gold standard for determining the degree of fetal anemia. IUT is not used before 18 weeks' GA because umbilical vein access is not reliable. For cases requiring earlier intervention, fetal intraperitoneal transfusion of red cells may initially be the intervention of choice.[29]

IUTs are typically performed using local anesthesia and require minimal maternal sedation and analgesia. However, the anesthesiologist should be prepared for an emergent cesarean delivery at any time during the procedure if the fetus is at a viable GA. Using ultrasound image guidance, a 20- or 22-gauge needle is used to access the umbilical vein. The access point is typically near the placental cord insertion to provide stability (Fig. 63.1). Puncture of an umbilical artery rather than the umbilical vein is associated with prolonged bleeding and fetal bradycardia secondary to spasm.[18] Occasionally a free loop of the umbilical cord or intrahepatic portion of the umbilical vein may be used. The umbilical cord has no known pain receptors, but needle access of the intrahepatic portion of the umbilical vein stimulates pain receptors with passage of the needle into the fetus. Fentanyl attenuates the fetal stress response from intrahepatic fetal needle placement.[30] In one study, fetal stress hormone changes with IUT were unrelated to site of needle placement;[31] however, these results are difficult to interpret because hormone levels may be affected by changes due to the underlying fetal anemia and hemodynamic alterations associated with intravascular volume expansion. Given this uncertainty, fentanyl (10-20 µg/kg) is administered intramuscularly to the fetus before use of an intrahepatic approach. There is some evidence to suggest that fetal anesthesia does not alter MCA peak systolic velocity flow patterns following transfusion.[32]

An intramuscular muscle relaxant (e.g., rocuronium 2.5 mg/kg) can be administered to the fetus to decrease the likelihood of fetal movement that could dislodge the needle or sheer the umbilical vein.[33] If a muscle relaxant is administered directly into the umbilical vein the dose of muscle relaxant can be reduced (e.g., rocuronium 1.0 mg/kg). The volume of type O, rhesus (Rh)-negative, irradiated, viral screened, packed RBCs transfused is estimated from the GA, estimated fetal weight, donor unit hemoglobin (Hb), and pretransfusion Hb.[34] The rate of transfusion is typically 5 to 10 mL/min with a target hematocrit of 45% to 55%. Steady intravascular location of the needle tip can be assessed with Doppler imaging throughout the transfusion injection. Periodic sampling is used to guide the final transfusion volume. After IUT therapy, fetal Hb levels decrease approximately 0.3 g/dL/day[35] and multiple repeat IUTs are typically required at 1- to 3-week intervals, depending on the rate of Hb decline.

Perinatal fetal loss rate is approximately 2% per IUT, and transient fetal bradycardia (8%) is a common complication.[27,36] Other complications including emergency cesarean delivery, intrauterine infection, preterm PROM, and preterm delivery occur in approximately 3% of IUT procedures.[37] Although survival rates are significantly less for hydropic fetuses, recent published overall survival rates with IUT typically exceed 95%.[27,37] A long-term outcome study of 291 children (median age of 8.2 years with a range of 2-17 years of age) who underwent IUT during gestation for hemolytic disease found a 4.8% rate of neurodevelopmental impairment, including cerebral palsy (2.1%), severe developmental delay (3.1%), and bilateral deafness (1.0%).[38] Severe fetal hydrops was independently associated with neurodevelopmental impairment.

CONGENITAL HEART DEFECTS

Congenital heart anomalies occur with a frequency of approximately 1/100 live births (see also Chapter 78).[39] Ventricular septal defects are the most common cardiac anomaly.[40] The majority of cardiac heart defects are not amenable to fetal intervention. Ultrasound imaging allows diagnosis of cardiac defects as early as 12 to 16 weeks gestation, but is generally performed at 18 to 22 weeks gestation, when obstetric ultrasound assessments are used to screen for other fetal abnormalities.[41]

The majority of fetal surgical cardiac interventions focus on opening a stenotic valve or enlarging a restricted opening. These include (1) aortic balloon valvuloplasty for treatment of critical aortic stenosis and evolving hypoplastic left heart syndrome (HLHS), (2) atrial septostomy for highly restrictive or intact atrial septum seen in HLHS,

(3) pulmonic valvuloplasty for pulmonary atresia or intact ventricular septum and hypoplastic right ventricles, and (4) pericardiocentesis to treat congenital cardiac tumors or aneurysms.[41-43a] In utero intervention attempts to halt or reverse the morbid effects of the cardiac lesion before irreversible consequences occur. Early childhood mortality from severe cardiac defects, such as HLHS, remains in the range of 25% to 35%.[44,45] Survivors have significant associated abnormalities in neurologic development.[46,47]

The most commonly performed procedure is an aortic valvuloplasty for aortic stenosis with evolving HLHS. Significant aortic stenosis maintains fetal circulation primarily through the low-resistance foramen ovale and diminishes left ventricular development. Selection guidelines for fetal aortic valvuloplasty focus on the presence of significant aortic stenosis, evolving HLHS, and the potential for a technically successful procedure and biventricular postnatal outcome.[48,49] For this procedure,[50] the fetus is ideally positioned with the left chest anterior, and ultrasound is used to guide the percutaneous passage of an 18- or 19-gauge needle cannula through the uterus, through the fetal chest, and into the apex of the left ventricle (Fig. 63.2*A*). Maternal local anesthesia infiltration or neuraxial block is typically used for these procedures, and fetal resuscitation drugs must be readily available. In some cases, general anesthesia may be preferred for uterine relaxation to facilitate an external version to change fetal position and improve cannula trajectory. Before cannula insertion, intramuscular fentanyl and a paralytic agent are administered to the fetus with ultrasound guidance, as detailed in the section on "Fetal Anesthesia, Analgesia, and Pain Perception."[51]

The cannula tip is ideally positioned in the left ventricle, directly in front of the opening of the stenotic aortic valve and aligned with the left ventricular outflow tract. A coronary balloon catheter with guidewire is passed through the cannula into the stenotic valve and positioned in the aortic annulus, where it is inflated and deflated multiple times (see Fig. 63.2*B*). In certain cases, a small laparotomy is used to facilitate improved cannula alignment with the cardiac lesion. Technical success for fetal aortic valvuloplasty is approximately 75% using an angioplasty balloon over a guidewire.[51a] Technical success creates improved left ventricular function, improved aortic and mitral valve development, and birth of a live neonate in 90% of interventions.[52,53] Fetal complication rates from centers in Linz, Austria ($n = 24$) and Boston ($n = 70$) for fetal aortic valvuloplasty include: fetal bradycardia (17% and 38%, respectively), pericardial effusion (13% and 14%, respectively), ventricular thrombosis (21% and 15%, respectively), and fetal death (13% and 8%, respectively).[48,54,55] A recent systematic review noted complication rates following fetal aortic valvuloplasty of preterm delivery (16%), neonatal death (16%), bradycardia (52%), and hemopericardium (20%).[43] Approximately 40% of technically successful cases result in aortic regurgitation and minimal subsequent left ventricular growth. Biventricular circulation is present at birth in approximately half of the successful cases.[43a]

In addition to treatment of aortic stenosis, other cardiac anomalies have been treated in utero. Similar surgical techniques are used for atrial septoplasty and pulmonary valvuloplasty.[42] Outcomes from a small series of fetal atrial septostomies are promising; however, the defect created

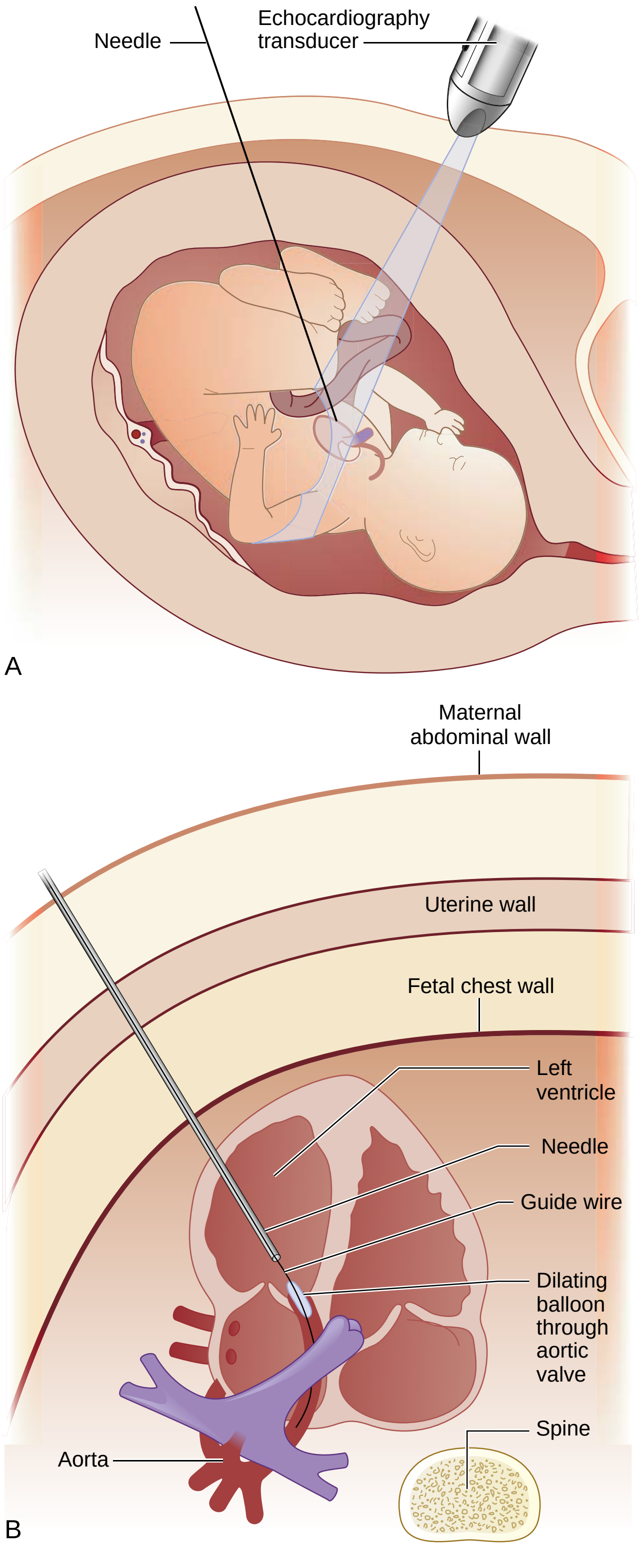

Fig. 63.2 (A) Depiction of ideal fetal position and insertion needle orientation. The fetal left chest is anterior, and the pathway from maternal abdomen entry point to the apex of the left ventricle is unobstructed. (B) This linear cannula course continues from left ventricle apex to the aortic valve. (Redrawn from Tworetzky W, Wilkins-Haug L, Jennings RW, et al. Balloon dilation of severe aortic stenosis in the fetus: potential for prevention of hypoplastic left heart syndrome—candidate selection, technique, and results of successful intervention. *Circulation.* 2004;110:2125–2131; with permission from Lippincott Williams & Wilkins.)

by the balloon dilation tends to close over time unless a stent is placed (which can be difficult and deployment has been successful in only 44%-62% of the time in a small case series).[56] Pulmonary valvuloplasty for pulmonary atresia and prevention of hypoplastic right ventricle was technically successful in 7 of 11 procedures, but long-term outcome data are unavailable.[42,57,58] In utero placement of cardiac pacing has been investigated to treat fetal cardiac arrhythmias unresponsive to conventional management with transplacentally administered antiarrhythmic drugs.[59,60] Unfortunately, these initial attempts have been frequently unsuccessful.

OBSTRUCTIVE UROPATHY

Fetal LUTO affects 2 in 10,000 live births.[61] These obstructions can be bilateral or unilateral and occur at the ureteropelvic junction, at the ureterovesical junction, or at the level of the urethra. If the obstruction is urethral or bilateral, significant developmental consequences occur (Box 63.1). Rates of perinatal mortality in these cases are as high as 90%, and survivors have more than 50% renal impairment.[62,63]

Posterior urethral valves are the most common cause of congenital bilateral hydronephrosis in male fetuses. Urethral obstruction is the most common cause in females, with other possible causes including ectopic ureter, ureterocele, megacystis megaureter, multicystic kidney, or other complex pathologic processes.[63,64] Ultrasound investigations of oligohydramnios resulting from decreased fetal urine output easily detect these uropathies with high sensitivity and specificity. Fetal MRI should be considered in cases of severe oligohydramnios as an additional imaging technique to determine the presence of associated fetal anomalies.[65] Grading systems based on ultrasound imaging of renal diameter to determine the severity of hydronephrosis and assessment of urinary tract dilation are used to determine risk stratification and treatment options.[66] Recently, a classification system for LUTO has been proposed that is based on amniotic fluid index, renal imaging, and fetal urine chemistry.[67] The associated morbidity predicted for each type of uropathy depends on obstruction location, duration, gender, and GA at onset.[68] Preterm delivery allows neonatal urinary tract decompression, but morbidity from pulmonary immaturity prevents early intervention and limits the efficacy of this approach.

Poor prognosis is associated with earlier presentation during gestation, more severe oligohydramnios, associated structural abnormalities, and increased concentrations of fetal urine electrolytes, osmolality, protein, and β_2-microglobulin.[68,69] Each case should be thoroughly investigated to determine whether other anomalies are present and if the fetus is a suitable candidate for intervention. If LUTO is corrected postnatally, 25% to 30% of surviving neonates will require dialysis by age 5.[70]

Placement of an in utero fetal vesicoamniotic shunting (VAS) for in utero treatment of LUTO allows decompression of the fetal bladder and urinary tract into the amniotic cavity. VAS prevents urine accumulation, allows normal bladder emptying and development, improves dysplastic renal histologic conditions, increases amniotic fluid volume, improves lung development, and prevents bladder wall fibrosis in animal models.[71-73] Determination of which human fetuses would benefit from in utero treatment of LUTO remains uncertain.[70,74] Human VAS placement started in the 1980s in an effort to improve renal development and reduce the pulmonary hypoplasia associated with oligohydramnios. These valveless, double-coiled shunts are inserted percutaneously with ultrasonographic guidance and local anesthesia. One coil remains in the urinary bladder and the other in the amniotic cavity. Prior infusion of fluid into the amniotic cavity can aid in proper shunt placement. Complications associated with these shunts include difficult placement, subsequent occlusion, and position migration (malfunction occurs in up to 60% of cases).[75] Fetal and maternal complications include fetal trauma, iatrogenic abdominal wall injury, gastroschisis, amnioperitoneal leaking, preterm PROM, preterm labor and delivery, and infection.[61] Neonatal survival rates after fetal VAS vary in the literature from 40% to 90%, with approximately 50% of survivors having normal renal function.[70,76-78] A meta-analysis of LUTO treatment studies through 2015 noted a perinatal survival advantage with in utero VAS placement compared to standard care (57% vs. 39%), but ultimately there was no difference in renal function or 2-year survival.[70] A multicenter, randomized controlled trial (the Percutaneous Shunting in Lower Urinary Tract Obstruction [PLUTO] trial) compared the perinatal mortality and renal function of fetuses with LUTO treated by either VAS or conservative noninterventional care. The trial was unable to recruit sufficient cases, with only 31 out of 150 desired patients recruited over a 4-year period. Analysis of this smaller enrollment noted a mortality benefit in the fetal treatment group at 28 days, 1 year, and 2 years of age; however substantial morbidity occurred in both groups, leading to only two children with normal renal function at 2 years of age.[79]

Fetal cystoscopy is a recent intervention that allows prenatal visualization of the fetal urethra and ablation of the urethral obstruction. Cystoscopy facilitates diagnosis between LUTO resulting from urethral atresia and posterior urethral valves. This is an important distinction, as urethral atresia is nearly universally lethal and does not improve with VAS placement, while posterior urethral valves are amenable to fetal intervention. Ablation of

posterior urethral valves may increase survival compared with expectant management. A case series[80] and retrospective case control study[81] demonstrated that fetoscopic laser ablation for posterior urethral valves can achieve bladder decompression and amniotic fluid normalization. In addition, fetal cystoscopy may improve 6-month survival in severe LUTO compared to no fetal intervention and result in improved renal function at birth when compared to treatment with VAS.[81] Future prospective trials are necessary to validate these initial retrospective results.

Selective fetal intervention with shunting or cystoscopy for LUTO restores amniotic fluid volume, prevents pulmonary hypoplasia, and improves perinatal mortality. However, the effects on medium-term and long-term renal function, neurologic function, bladder function, and other morbidities remain unclear and additional clinical research is needed.[74,82]

Twin Reversed Arterial Perfusion Sequence

Twin reversed arterial perfusion (TRAP) sequence is an abnormality of monozygotic twins that affects approximately 1 in 35,000 pregnancies, 1 in 100 monozygotic twin gestations, and 1 in 30 triplet gestations.[83] In this condition, one of the monozygotic twins has an absent or nonfunctioning heart and no connection to the placenta. The nonviable twin is perfused with retrograde blood flow from the other twin through vascular anastomoses. Blood returns to the normal twin by anastomoses that bypass the placenta. The inadequate perfusion of the recipient twin (primarily occurring retrograde through the umbilical artery) results in a lethal set of anomalies that include acardia and acephalus. Because the normal or “pump” twin generates blood flow for both itself and the nonviable twin, it is at risk for high-output congestive heart failure, hydrops fetalis, and preterm birth secondary to the increased uterine volume from polyhydramnios and increased size of the hydropic nonviable twin.[84,85] If untreated, TRAP sequence is associated with a 35% to 55% risk for intrauterine death of the normal pump twin, with survivors having an average GA of only 29 weeks.[86,87] Diagnosis is confirmed by reverse flow to the nonviable twin via the umbilical artery on ultrasound. The objective of fetal therapy is to disrupt the vascular communication between the two twins in an effort to prevent further cardiac failure in the pump twin. Successful treatment of TRAP sequence results in cessation of flow in the recipient twin’s umbilical artery and the death of the nonviable fetus.

Several in utero approaches can accomplish these goals. Ultrasound-guided umbilical cord coagulation using laser, radiofrequency, or bipolar techniques, fetoscopic laser coagulation of placental anastomoses, and percutaneous intrafetal laser or radiofrequency ablation of the acardiac twin’s umbilical cord base appear to be the most viable therapeutic options (Fig. 63.3).[88-90] Additional interventions include selective delivery of the nonviable fetus by hysterotomy, umbilical cord ligation, cord transection, and cord coagulation using coils or other thrombogenic material. Ablative techniques are likely superior to cord ligation or occlusion techniques.[88,91] A multicenter retrospective review of 98 TRAP sequence cases treated with radiofrequency ablation noted survival rates of 80% and a median GA at delivery of 37 weeks.[89] Although it is difficult to determine the optimal timing and treatment option, the therapeutic benefit of ablative intervention as early as 12 weeks GA has been demonstrated, as significant cardiac failure and death may occur in up to a third of pump twins if therapy is delayed until after 16 weeks gestation.[88,91,92] The most common complications following TRAP treatment include preterm PROM, preterm delivery, and intrauterine fetal demise.

Minimally invasive procedures to treat TRAP typically only require infiltration of local anesthesia at the percutaneous insertion site of the fetoscope or ablative device, although neuraxial anesthesia can also be used. Ultrasound guidance and assessment is critical for all of these therapies, and procedure success is confirmed by absence of flow to the nonviable acardiac twin at the end of the procedure and again approximately 12 to 24 hours later.

TWIN-TO-TWIN TRANSFUSION SYNDROME

Monochorionic twins share the same placenta and typically have intertwin vascular connections that create shared blood flow between the two fetuses. A significant number of these chorionic vascular anastomoses can result in unequal placental blood flow between the two monochorionic twins that can lead to twin-to-twin transfusion syndrome (TTTS). The occurrence of TTTS is approximately 1 to 3/10,000 births.[93] Monochorionic twinning occurs in approximately 20% to 25% of twin pregnancies, with TTTS complicating about 10% of these monochorionic gestations.[93-95] TTTS

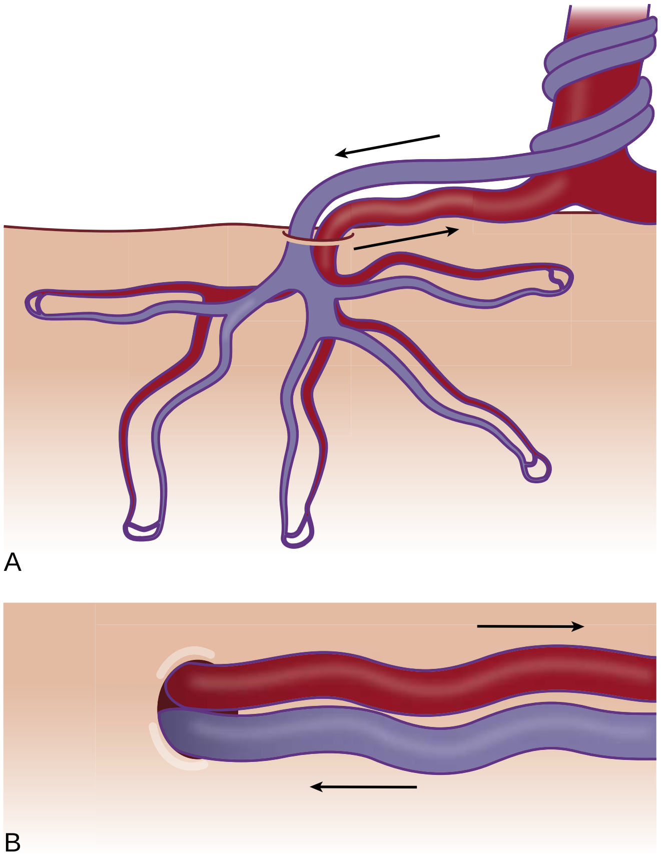

Fig. 63.4 (A) Normal placenta angioarchitecture (cotyledon). (B) Superficial view of bidirectional flow into and out of a cotyledon. (Redrawn from Rand L, Lee H. Complicated monochorionic twin pregnancies: updates in fetal diagnosis and treatment. *Clin Perinatol.* 2009;36:417–430.)

usually manifests after the first trimester and is typically recognized at midgestation.[94,96]

Normally, umbilical arteries carry deoxygenated blood to the surface of the placenta, where gases and nutrients are exchanged with the maternal circulation. The returning venous blood flow is "paired" with the arterial flow, and the two components lie next to each other (Fig. 63.4). This fetal-placental vascular configuration (cotyledon) represents normal anatomy. A variety of abnormal unidirectional and imbalanced vascular connections are present in TTTS (Fig. 63.5). In TTTS, a branch of an umbilical artery descends into the placenta and cotyledon, but instead of connecting with a paired vein, it connects with a vein that brings blood to the other twin, and this results in an arteriovenous anastomosis between the two fetuses.[94,96] Although some intertwin arteriovenous vascular architecture is found in 90% to 95% of all monochorionic twins, the shared blood flow is balanced by the presence of arterioarterial and venovenous bidirectional connections, which are found in 85% to 90% and 15% to 20% of monochorionic twin placentas, respectively.[94,97,98] The presence of arterioarterial connections is viewed as protective by allowing the overall resistance and blood flow to equalize between the twins and is associated with a significant reduction in TTTS.[99]

The complex pathophysiology of TTTS is dynamic and secondary to a variety of humoral, biochemical, hemodynamic, and functional changes in the two fetuses.[94] The increased blood flow to the recipient twin leads to polycythemia, polyuria, and polyhydramnios and can cause hypertrophic cardiomyopathy, hydrops fetalis, and fetal death. The donor twin (often described as the "stuck" or "pump" twin) is typically hypovolemic, growth-restricted, confined against the endometrium in an oligohydramniotic sac. This twin is primarily at risk for renal failure, cardiac failure, and hydrops fetalis secondary to the high cardiac output state.

The diagnosis of TTTS requires (1) a monochorionic diamniotic pregnancy and (2) a significant discrepancy in amniotic fluid volumes with ultrasound measurements of the maximal vertical pocket (MVP) of less than 2 cm in the oligohydramniotic twin and the MVP greater than 8 cm in the polyhydramniotic twin.[94,100] Twin size discordance and the presence of intrauterine growth restriction are often present in TTTS, but are not considered necessary to confirm the diagnosis. Although a variety of staging systems exist for determining the severity of TTTS, the most commonly used is the Quintero staging system (Table 63.2), which is based on ultrasound findings.[101,102] The progression of hypertrophic cardiomyopathy in the fetal recipient is detailed in a scoring system presented by Rychik and colleagues utilizing fetal echocardiography[103,104] that provides a more detailed assessment of TTTS severity when combined with the Quintero staging system.[95]

Fetuses with TTTS are at risk for preterm PROM, preterm delivery, and neurologic injury with white-matter lesions and long-term disability.[105] Neurodevelopmental impairment is associated with a low GA at birth.[106-108] Although outcome data stratified for the advanced stages of TTTS are limited, a higher mortality rate is likely associated with more advanced progression of disease.[100,109] TTTS treatment at stage I has an 85% survival rate, while higher-staged TTTS can increase to greater than 80% mortality if untreated.[93,110]

Several therapeutic management techniques have been developed to treat TTTS. Amnioreduction can help control polyhydramnios and thereby reduce the risk for both preterm labor and maternal respiratory distress. Also, placental blood flow may improve by decreasing amniotic hydrostatic

TABLE 63.2 Stages of Twin-Twin Transfusion Syndrome

Stage	Ultrasound Findings
I	Amniotic Fluid: Oligohydramnios in donor twin sac with MVP < 2 cm and polyhydramnios in recipient twin sac with MVP > 8 cm
II	Fetal Bladder: Stage I criteria AND no visualization of donor twin bladder with over 1 h of ultrasound observation
III	Doppler Flow: Stage II criteria AND (1) absent or reversed umbilical artery end-diastolic flow, (2) reversed ductus venosus a-wave flow, OR (3) pulsatile flow in the umbilical vein
IV	Fetal Hydrops: Either stage I or stage II criteria AND fetal hydrops in either twin
V	Fetal Demise: Fetal demise in either or both twins as assessed by absent fetal cardiac activity

pressure on the placental vasculature. Serial amnioreductions have been used to treat TTTS for more than 25 years by improving placental perfusion and decreasing the rate of preterm deliveries.[111] A retrospective review of 223 twin sets with TTTS found that use of amnioreduction resulted in an overall birth survival rate of 78%, with survival rates of 65% for recipient twins and 55% for donor twins at 1 month of age.[112] Another review of 112 TTTS cases reported a 61% perinatal survival rate with use of amnioreduction.[113]

Use of an ultrasound-guided needle to create a surgical septostomy was hypothesized to improve TTTS outcome by equalizing the amniotic pressure between the two fetal sacs. In a prospective randomized trial comparing serial amnioreduction to septostomy, no survival difference was found between the techniques.[114] Septostomy is rarely used now for TTTS treatment because it offers no outcome advantage, and the creation of a single amniotic sac can increase the risk for umbilical cord entanglement. Selective feticide with the goal of improving the chance for survival of the other twin is accomplished using techniques described previously in the section on TRAP sequence. This option is typically used only for the most severe cases of TTTS.

Selective fetoscopic laser photocoagulation (SFLP) of the vascular anastomoses between the two twins is the best therapeutic approach for treating TTTS (stages II-IV) between 18 and 26 weeks gestation.[94,95,115] By detailed fetal ultrasound examination, the location of the placenta, cord insertions, and fetal orientation and anatomy are confirmed before the start of the procedure. Local anesthesia infiltration with monitored anesthesia care is a common anesthetic technique, though neuraxial anesthesia can also be used. Using ultrasound guidance, a 3-mm trocar or cannula is inserted percutaneously over a wire into the recipient twin's amniotic sac and directed perpendicular to the longitudinal axis of the donor twin.[115] The fetoscope is inserted into the trocar sheath and the laser fiber bundle passed into the fetoscope guide. Vessels that cross the membrane dividing the amniotic sacs are visualized and Doppler imaging can be used to confirm flow magnitude and direction. The abnormal connecting vessels are selectively laser coagulated, with an effort to spare the normal cotyledons.[7,96] Ideally this delineates two separate placental regions with each supplying an individual fetus. After laser ablation, amnioreduction is also performed in an effort to decrease the risk for preterm labor. Nonselective laser ablation of crossing vessels is typically avoided because it is associated with more frequent rates of intrauterine fetal demise and is likely to unnecessarily ablate some normal placental vessels.[101,115] Ablation of all abnormal connecting vasculature is not necessary for the procedure to be successful.[116] Some practitioners advocate use of a sequential technique when coagulating the various types of abnormal anastomoses in an effort to create a net flux of blood from the recipient to the donor and thereby reduce the chance for hemodynamic compromise and hypotension during the procedure in the donor twin.[117] Initially, superficial arteriovenous anastomoses that contain a donor artery are ablated, then arteriovenous anastomoses with a recipient artery, then the arterioarterial anastomoses, and finally ablation is performed at the venovenous anastomoses. A prospective multicenter trial comparing use of sequential SFLP to nonsequenced SFLP found that use of sequential SFLP significantly improved the 30-day survival of both twins and decreased fetal demise.[118,119] However, use of this sequential technique is associated with longer operative times and increased case difficulty, particularly with a placenta located on the anterior uterine wall. A recent modification of SFLP called the "Solomon technique" was created to reduce recurrent TTTS.[120] In the Solomon technique, the entire vascular equator is coagulated following the coagulation of visible vessels, in order to reduce residual anastomoses. A randomized controlled trial comparing SFLP to the Solomon technique trial noted that the Solomon technique reduces the risk of recurrence of TTTS or twin-anemia polycythemia sequence following initial treatment, but no difference in 2-year survival without neurodevelopmental disability was found.[121,122]

A 2004 randomized multicenter trial compared SFLP therapy to amnioreduction for treatment of severe TTTS diagnosed between 15 and 26 weeks gestation.[123] Rates of at least one twin survival were more frequent in the laser treatment group at both 28 days (76% vs. 56%, $P < .01$) and 6 months of life (76% vs. 51%, $P < .01$). In addition, neurologic outcomes were better in the laser treatment group. A large subgroup of survivors from this trial was followed prospectively for 6 years. No additional change in either survival rate or long-term neurologic outcome was found in comparison to the original 6-month data.[124] This conclusion was echoed in a 2014 Cochrane review of laser treatment for TTTS.[110] More recent work has suggested that early intervention in stage I TTTS may be beneficial compared to expectant management.[125]

Although recent SFLP treatment studies of TTTS studies suggests a greater than 60% dual survival rate and near 90% survival of at least one twin,[126] long-term neurologic outcome in TTTS survivors who underwent SFLP remains unclear, with rates of major neurologic abnormalities in survivors ranging from 3% to 25%.[124,127] A recent review of 9 studies examining neurodevelopmental outcomes at 24 months in patients who underwent laser therapy found a mean rate of neurological injury of 14%. The mean rate of cognitive impairment was 8%, 11% for motor delay, 17%

for communication delay, and 6% for cerebral palsy.[105] Neonatal cerebral lesions correlate with neurodevelopmental impairment at 2 years of age.[128]

The most common complication of SFLP is preterm PROM with subsequent preterm labor and delivery. Preterm PROM rates vary widely across studies, but have been reported to occur in 12% to 30% of SFLP cases for TTTS with a rate of preterm labor and delivery before 32 weeks gestation of approximately 30%.[94,95] Other possible complications include placental abruption, need for a second SFLP procedure, placement of the trocar through the placenta, hemorrhage, chorioamnionitis, and possible membrane perforation resulting in limb entrapment and ischemia.[94,95]

In conclusion, treatment of TTTS with SFLP results in better outcomes compared to amnioreduction alone.[126] Additional research is needed to determine optimal timing, further technique refinement, and long-term neurologic outcome for the treatment of TTTS with SFLP.

AMNIOTIC BAND SYNDROME

Amniotic band syndrome (ABS) includes a wide variety of fetal anomalies associated with fibrous bands that entangle or constrict various parts of the fetus or umbilical cord in utero (Fig. 63.6). The resulting malformations include limb and digit amputations, craniofacial abnormalities, visceral defects, and body wall defects. The incidence is approximately 1 in 3000 to 1 in 15,000 live births.[129] The primary cause and pathogenesis of ABS remains unknown, but these defects appear secondary to either a vascular insult or other cause of abnormal perfusion to the affected area.[130] Theories behind the cause of ABS include a primary defect in embryonic development, an early amniotic membrane rupture resulting in the creation of amniochorionic bands, or a vascular disruption early in pregnancy.[131]

Diagnosis is determined by findings on ultrasound imaging consistent with characteristic fetal anomalies of the involved anatomy. Visualization of the bands themselves is not a necessary component of the diagnosis.[132] Fetal MRI can aid in diagnosis as a complementary technique to ultrasound, but the efficacy of its use is currently limited to case reports and a small case series.[133] The progression of morbid conditions from each case of ABS is difficult to predict. In cases of limb entrapment, increasing band constriction decreases both venous and arterial flow. This decreased perfusion leads to limb edema and can eventually result in amputation distal to the constriction. In an otherwise normal fetus, use of fetoscopic-guided sectioning of the band with a laser can restore distal blood flow and may improve functional outcome in some cases.[131] Efficacy of the technique is based on review of a small number of cases in the literature, which range from 50% to 80% of limb form and function preservation provided that some arterial flow to the affected limb is present pre-intervention.[134,135] Single limb involvement is also associated with a more favorable surgical outcome compared to fetuses with multiple limb involvement.[135] Interestingly, the rate of PROM in these procedures is higher than other fetoscopic procedures.[129,131] ABS can also be an iatrogenic complication following minimally invasive fetal procedures in monochorionic diamniotic twins, and should be evaluated for especially if known chorioamnion separation or septostomy occurs.[136]

Fig. 63.7 Depiction of congenital diaphragmatic hernia. A defect in the fetal diaphragm allows abdominal contents (e.g., intestines, liver) to enter the thoracic cavity, compress the heart, and prevent lung growth and maturation. (Redrawn from Graves CE, Harrison MR, Padilla BE. Minimally invasive fetal surgery. *Clin Perinatol.* 2017;44(4):729–751.)

CONGENITAL DIAPHRAGMATIC HERNIA

Approximately 1 in 2500 newborn infants has a congenital diaphragmatic hernia (CDH).[137] During early gestation, abdominal contents herniate into the thoracic cavity and compress the fetal lungs (Fig. 63.7). This results in significant neonatal morbidity and mortality from pulmonary hypoplasia, respiratory insufficiency, and pulmonary hypertension. CDH survival rates when ECMO is not required have improved to greater than 70% over the past 25 years at tertiary care centers.[138,139] These highly specialized centers offer care that includes early intubation, surfactant administration, ventilation techniques to minimize lung trauma, surgical closure of the defect, and ECMO therapy. Mortality rates vary greatly with the severity of pulmonary hypertension and respiratory dysfunction.[140,141] If ECMO is required, survival rates vary between 50% and 80%.[139] Fetal intervention for CDH aims to improve fetal lung development and prevent the morbidity of pulmonary hypoplasia.

In utero repair of diaphragmatic hernia in lamb models reversed both the parenchymal hypoplasia and pulmonary vascular changes associated with CDH.[23] Initial human in utero intervention focused on open repair of the fetal diaphragm with limited success.[142,143] However, these initial interventions advanced fetal surgery techniques and paved the way for a minimally invasive approach to CDH intervention.

Initial open intervention experience found that a fetal abdominal patch was necessary to accommodate the added abdominal viscera without increasing intraabdominal pressure and compromise of ductus venosus blood flow. These early open interventions also determined that in utero reduction of the herniated liver compromised umbilical circulation and significantly increased fetal mortality. Additionally, the advantage of opening the uterus with a stapling device to ensure effective hemostasis was demonstrated. However, adequate control of postoperative uterine tone remained a substantial problem. In a prospective clinical trial sponsored by the National Institutes of Health, in utero CDH treatment using an open technique for fetuses without herniation of the liver into the thorax did not improve neonatal survival compared with standard postnatal treatment.[144]

After these efforts, tracheal occlusion was advanced as a less-invasive strategy for treating fetal CDH and improving lung development. Fetal lungs secrete over 100 mL/kg/day of fluid that exits the trachea and mouth into the amniotic cavity. In fetal lamb models, tracheal occlusion restricts the normal outflow of the fetal lung fluid and provides an increase in pulmonary hydrostatic pressure. This increased pressure pushes the viscera out of the thorax, promotes expansion of the hypoplastic lung, and thereby improves lung growth and development.[145,146] Fetal reversible tracheal occlusion[147-149] has replaced primary repair in utero for the treatment of CDH. Initially, a tracheal foam plug was inserted in the fetal airway during open surgery, but it failed to provide adequate occlusion.[150] Later, metallic hemoclips were placed around the trachea after meticulous neck dissection.[150] Unfortunately, survival with this initial open tracheal occlusion procedure was poor (15%) and lower than survival in CDH fetuses receiving postnatal standard treatment (38%).[151]

Subsequently, minimally invasive fetal endoscopic surgical techniques replaced the open technique for placement of the clips. These procedures are performed with local or neuraxial maternal anesthesia and the administration of fetal anesthesia by intramuscular injection. A variety of occlusive devices, including cuffs, plugs, valves, and balloons, were attempted at various medical centers.[152] Currently, percutaneous endoscopic endotracheal intubation is used to place a small detachable occlusive balloon in the fetal trachea.[149] With initial procedures the balloon was left in place until delivery (see discussion on EXIT procedures), but currently, it is deflated and removed before term with a second fetal endoscopy.[153] The balloon removal may improve type II pneumocyte function, increase surfactant production, and allow a vaginal delivery when appropriate.[152]

TABLE 63.3 Postnatal Survival in Fetuses With Left-Sided Congenital Diaphragmatic Hernia and Intrathoracic Liver Herniation Based on Fetal Lung to Head Ratio

LHR, Lung area-to-head circumference ratio.

Modified from Jani JC, Nicolaides KH, Gratacos E, et al. Fetal lung-to-head ratio in the prediction of survival in severe left-sided diaphragmatic hernia treated by fetal endoscopic tracheal occlusion (FETO). *Am J Obstet Gynecol*. 2006;195:1646–1650.

Use of ultrasound imaging to determine the ratio of fetal lung area to head circumference (LHR) and the presence of thoracic liver herniation ("liver up" vs. "liver down") are historically the most reliable prognostic indicators of fetal CDH outcome.[152,154,155] Evaluation of survival in fetuses with left-sided CDH and intrathoracic liver herniation managed postnatally noted no survival with an LHR of 0.7 or less and a survival rate of 72.7% or greater with an LHR of 1.4 or greater (Table 63.3).[154] The LHR increases exponentially with GA and is less useful after 28 weeks gestation.[156] The Antenatal CDH Registry Group normalized the LHR to GA by creating an observed to expected LHR (o/e LHR)[157] that correlates well with survival rate (Fig. 63.8).[158,159] More recently, fetal MRI measurement of observed to expected total fetal lung volume (o/e TFLV) correlates well with neonatal survival in fetuses with isolated CDH as an assessment of pulmonary hypoplasia.[160,161] In addition to presence of liver herniation, use of a 25% threshold with o/e LHR and o/e TFLV appear to perform the best as predictors of survival with CDH.[159]

A prospective randomized trial (1999-2001) evaluated fetal endoscopic tracheal occlusion (FETO) for prenatal treatment of CDH using both clip and balloon occlusion techniques.[162] Inclusion criteria included a 22- to 28-week GA, left-sided thoracic liver herniation, and an LHR of less than 1.4. The trial was closed early, and no benefit in survival or reduction in 90-day morbidity was found with prenatal treatment (n = 11) compared with control (n = 13) (survival rates of 73% vs. 77%). Additionally, rates of PROM and preterm delivery were more frequent in the fetal intervention group, with 100% of the fetoscopic intervention group having PROM.[162] The inclusion of fetuses with an LHR of up to 1.4 may have decreased the ability to determine a significant difference, because many of these fetuses were likely to survive with standard postnatal tertiary medical care (see Table 63.3).

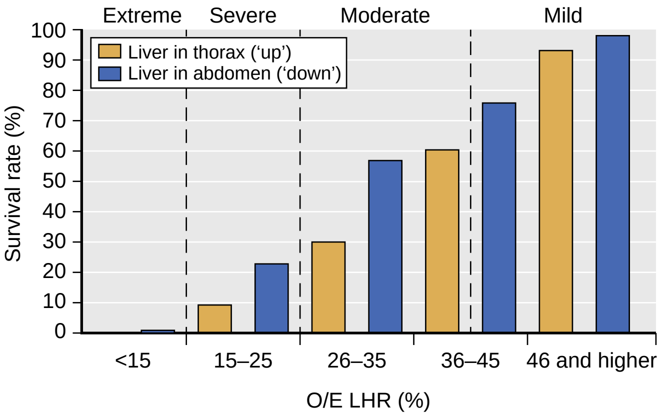

Fig. 63.8 Survival rates of fetuses with isolated left-sided congenital diaphragmatic hernia, depending on measurement of the observed to expected lung area to head circumference ratio *(O/E LHR)* and position of the liver. (Redrawn from Deprest JA, Nicolaides K, Gratacos E. Fetal surgery for congenital diaphragmatic hernia is back from never gone. *Fetal Diagn Ther.* 2011;29:6–17.)

Three European medical centers and the FETO task force began a collaboration for treatment of severe cases of CDH with a high risk for mortality (LHR < 1.0 and liver herniation into the hemithorax).[157,163] Because of concern for tracheal damage by very early tracheal balloon placement,[164] the tracheal balloon was placed at 26 to 28 weeks gestation and removed around 34 weeks gestation. Data from FETO task force cases through 2008 ($n = 210$, mean GA of placement at 27 weeks, LHR < 1.0, and primarily left-sided CDH) were compared with historic postnatal treatment controls (1995-2004). Use of prenatal reversible tracheal occlusion significantly improved the survival rate (47% vs. 20% in historic controls), and delivery occurred at a median GA of 35 weeks.[163] In addition, mean operating time was minimal (<10 minutes) and more than 95% of procedures were successful on the first attempt. Some of the survival benefit with in utero treatment may represent selection bias as well as improvement in both technique and neonatal care over time.

A 2016 metaanalysis of all studies comparing survival outcome between FETO and a contemporary control group found fetal intervention improved survival in patients with isolated CDH and a LHR ≤ 1.0. Fifty-one of 110 fetuses (46.3%) who had undergone FETO survived to discharge, compared with 6 of 101 (5.9%) in the control group.[165] Another recent study suggests that patients undergoing FETO for severe isolated CDH have morbidity outcomes similar to those fetuses with moderate lung hypoplasia.[166] Although FETO improves lung growth, and decreases need for ECMO, left heart hypoplasia may persist until after the postnatal CDH repair.[167]

A multicenter randomized Tracheal Occlusion to Accelerate Lung growth trial is ongoing (http://www.totaltrial.eu).[168] It compares postnatal management to both late (30-32 weeks gestation) FETO intervention for moderate lung hypoplasia and earlier FETO intervention (27-30 weeks gestation) for severe lung hypoplasia. This trial uses o/e LHR criteria, and balloon occlusion removal is planned for 34 weeks gestation, with postnatal management standardized by a consensus protocol. Long-term outcome data on pulmonary and neurologic development are needed to better determine if and when FETO should be offered for individual cases of severe CDH. New data suggest that prenatal administration of sildenafil may further reduce neonatal pulmonary hypertension, with or without invasive fetal surgery.[149]

MYELOMENINGOCELE

Spina bifida includes all defects with incomplete neural tube closure. Myelomeningocele (MMC) is the most common type of spina bifida and results in exposure of the meninges and spinal cord through a congenital defect in the vertebrae and overlying tissues. MMC occurs during the third and fourth weeks of gestation with incomplete embryonic neural plate development. Folate supplementation in the maternal diet has decreased the rate of MMC by nearly 50%, but the benefit reached a plateau without eliminating the disorder and MMC remains at a rate of approximately 1 in 3000 live births.[169,170] Improved prenatal screening with α-fetoprotein measurement and ultrasonography allows the possibility of pregnancy termination, and it is estimated that 25% to 40% of MMC pregnancies are terminated. MMC can result in lifelong morbidity and disability, including loss of motor and sensory function based on lesion level, bowel and bladder dysfunction, sexual dysfunction, hydrocephalus, Arnold-Chiari type II malformation, tethered cord, and impaired cognition.[169,171] If uncorrected in utero, surgical closure of the spinal defect must be performed within a few days after birth. Children with lumbosacral MMC defects often require ventriculoperitoneal shunting for hydrocephalus.[172] Even with successful shunting, complications of central hypoventilation, vocal cord dysfunction, and swallowing difficulties can persist because of an associated Arnold-Chiari malformation.[173] The mean intelligence quotient in patients with MMC who underwent ventriculoperitoneal shunting is 80 (low normal)[174] and decreased compared to those who do not require a shunt.[175] Neonates with spina bifida have a 14% mortality rate by 5 years of age and a 35% mortality rate in those with known brainstem dysfunction and Arnold Chiari type II malformation.[169]

The cause of MMC remains unknown. The abnormalities and deficits of MMC are hypothesized to be the result of two separate mechanisms. The primary cause is anatomic malformation with abnormal development of the spinal cord and associated tissues. Secondary damage is likely created by exposure of these open neural elements to the amniotic fluid and direct trauma. Consequently, the ability to close the defect in utero and isolate the neural tissue from contact with the intrauterine environment has the potential to improve outcome in contrast to delaying closure until after birth.

This hypothesis has been supported by animal models that found improved neonatal neurologic function with fetal closure of the defect in utero.[176-179] Ultrasound assessment demonstrates that central and peripheral neurologic injury is progressive during gestation.[180,181] Motor deficits and cognitive dysfunction are correlated with lesion level and higher levels are associated with a greater degree of morbidity.[177] Improved motor function has been observed at 2 years of age in children with MMC who underwent cesarean delivery before labor onset compared to those delivered vaginally or by cesarean delivery after onset of labor.[169,182] Therefore, women with fetuses with MMC and planned postnatal repair typically undergo cesarean delivery before onset of labor or rupture of membranes in an effort to minimize any additional injury to the open neural elements.

The rationale for fetal intervention for MMC is to improve functionality and quality of life. Prenatal repair for MMC is most commonly performed with an open fetal surgery technique requiring both maternal laparotomy and hysterotomy, although a few centers have started performing the repair with an endoscopic fetal technique. Considerations for anesthesiologists involved in open MMC repair (see section on "Management of Open Procedure") include participating in comprehensive, multidisciplinary, preoperative maternal evaluation and counseling; preparing for potential intraoperative hemorrhage; planning an anesthetic that provides profound uterine relaxation; administering analgesia and muscle relaxant directly to the fetus; monitoring the need for potential fetal resuscitation or urgent delivery; and managing maternal analgesia and postoperative uterine and fetal monitoring.[183]

MMC in utero surgery typically occurs between 19 and 26 weeks gestation. Initial human studies found that in utero repair reversed the hindbrain herniation of the Arnold-Chiari II malformation and decreased the requirement for ventriculoperitoneal shunt placement before 1 year of age.[184] In addition, a 1999 series of 10 fetuses undergoing in utero MMC closure at 22 to 25 weeks gestation found improved lower extremity function among 6 out of 9 fetuses compared with expected function based on the level of lesion, with one fetal death at 25 weeks gestation from preterm delivery and associated respiratory insufficiency.[185] A randomized, prospective clinical trial completed between 2003 and 2010 at three U.S. medical centers examined the risks, benefits, and outcomes of open in utero repair for MMC compared with standard postnatal repair among 183 patients.[186] Open fetal repair reduced the need for ventriculoperitoneal shunting, decreased hindbrain herniation, and improved lower extremity motor function at 30 months of age. However, prenatal repair significantly increased the risk for various fetal and maternal complications,[8,186] including spontaneous membrane rupture, partial or complete uterine dehiscence, and preterm birth with increased risk for respiratory distress syndrome (Table 63.4). Two perinatal deaths occurred in each group. A 30-month follow-up study demonstrated that patients undergoing fetal surgery were more likely to have a level of function 2 or more levels better than expected (26.4% vs. 11.4%), to be able to walk independently (44.8% vs. 23.9%, $P = .004$), to perform better on the Bayley Mental Development Index, and to have improved Peabody Developmental Motor Scale.[187,188] Long-term outcomes from this trial are still ongoing, but a pretrial cohort of 54 patients undergoing fetal MMC repair reported improved functional and behavioral outcomes at age 10 years, especially among children who did not require ventriculoperitoneal shunting.[189]

Results of this trial should not be generalized to patients outside the inclusion criteria of the study and should be considered only at medical centers that can develop a practice with significant volume and depth of resources.[190] It is recommended that this procedure be offered only at medical facilities with the expertise, multidisciplinary teams, services, and facilities to provide the intensive care required for these patients, while maintaining rigorous patient selection.[191]

TABLE 63.4 Maternal Complications for Management of Myelomeningocele Study Trial Patients

	Prenatal ($n = 91$)	Postnatal ($n = 92$)	P
MATERNAL OUTCOMES			
Chorioamniotic membrane separation	30 (33%)	0	<.0001
Pulmonary edema	5 (6%)	0	.03
Oligohydramnios	19 (20%)	3 (3%)	<.001
Placental abruption	6 (7%)	0	.01
Spontaneous rupture of membranes	40 (44%)	7 (8%)	<.0001
Spontaneous labor	39 (43%)	13 (14%)	<.0001
Maternal blood transfusion at delivery	8 (9%)	1 (1%)	.02
Hysterotomy site thin, or partial or complete dehiscence noted at delivery	31 (35%)	N/A	N/A
Mean gestational age at birth (weeks)	34.0 ± 3.0	37.3 ± 1.1	<.0001

The table lists maternal complications that were significantly different ($P < .05$) between the prenatal and postnatal repair groups in the Management of Myelomeningocele Study (MOMS) following complete cohort analysis of 183 patients. Other outcomes were evaluated, but only those that were different between the two groups are included. Data for each group are shown as both an absolute number and as a percentage.

Modified from Johnson MP, Bennett KA, Rand L, et al. The Management of Myelomeningocele Study: obstetrical outcomes and risk factors for obstetrical complications following prenatal surgery. *Am J Obstet Gynecol*. 2016;215:778.e1–e9.

With improvement in surgical technique, and feasibility demonstrated in animal studies,[192] endoscopic MMC repair is increasingly practiced. In theory, a minimally invasive approach may reduce maternal complications and obviate the need for maternal cesarean delivery.[193] A phase I clinical trial of percutaneous endoscopic repair ($n = 10$) using a biocellular patch over the defect followed by skin closure revealed improved hindbrain herniation and motor function, however preterm delivery was significant with the mean gestational birth age being 32 weeks.[194] In addition, 2 of 10 procedures were aborted due to loss of uterine access, preterm PROM occurred in all 10 cases, and 1 fetus and 1 neonate died. Outcomes have improved with evolution of the fetoscopic repair technique to include a maternal laparotomy and exteriorization of the uterus prior to insertion of the fetoscope ports.[193,195] After port placement, a portion of amniotic fluid is withdrawn and carbon dioxide is insufflated. A retrospective cohort trial of 28 patients undergoing fetoscopic MMC repair (22 fetoscopic, 4 conversion to hysterotomy, 2 abandoned) noted a mean delivery at 39 weeks gestation with a standardized surgical approach ($n = 10$) using a two-port technique and a preterm PROM rate between 10% and 30%.[193] Of the 22 patients who underwent a fetoscopic repair, 50% delivered vaginally. Recently a method using partial amniotic carbon dioxide insufflation without pre-removal of amniotic fluid has been described and successfully used in MMC repair.[196]

A 2017 metaanalysis of 11 studies examining fetal MMC repair found no difference in mortality or need for ventriculoperitoneal shunt among fetal patients treated with an open or endoscopic technique.[9] Patients treated with a percutaneous fetoscopic technique had a higher PROM rate (91% vs. 36%), a higher risk of preterm delivery (96% vs. 81%), and a higher rate of cerebral spinal fluid leakage from the MMC repair site (30% vs. 7%). Fetal repair via a fetoscopic approach following maternal laparotomy had a lower rate of premature birth. Uterine dehiscence was higher in the open surgical group (11% vs. 0%). The authors concluded that a fetoscopic technique is a promising, though not yet perfected, technique for fetal MMC repair.[9] Minimally invasive endoscopic repair of MMC should still be considered an experimental treatment given the steep learning curve and lack of long-term outcome data.[7]

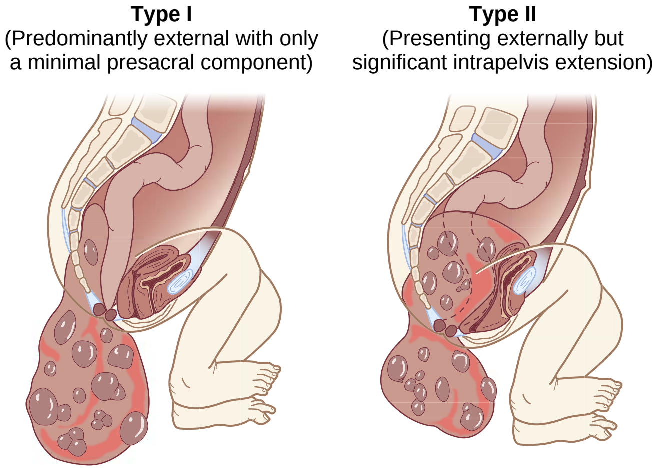
SACROCOCCYGEAL TERATOMA

The incidence of sacrococcygeal teratoma (SCT) is approximately 1 in 15,000 to 40,000 live births.[197] These teratomas are typically diagnosed by ultrasound in the second trimester of pregnancy and may grow rapidly (>150 cm^3/week), with some reaching sizes of 1000 cm^3 or more.[198] The larger tumors create a significant arteriovenous shunt and low resistance state and lead to the development of high-output cardiac failure, polyhydramnios, placentomegaly, and hydrops fetalis.[199] In addition, rapidly growing tumors may rupture and hemorrhage. Perinatal mortality varies greatly in different published series, ranging from 16% to 63%.[200] In addition, fetuses with SCT are at risk for preterm birth, intrapartum dystocia, tumor rupture with hemorrhage, and urinary obstruction. Cesarean delivery is frequently required.

Tumor staging is based on criteria from the American Academy of Pediatrics Surgical Section as detailed by Altman (Fig. 63.9).[201] Based on the external location, stage I tumors are suitable for fetal intervention whereas stage IV tumors are entirely internal and not considered appropriate for fetal resection.[198] Fetal MRI can assist in tumor size, location, and staging. A tumor volume to fetal weight ratio greater than 0.1 cm^3/g prior to 24 weeks gestation is predictive of poor fetal outcome.[202]

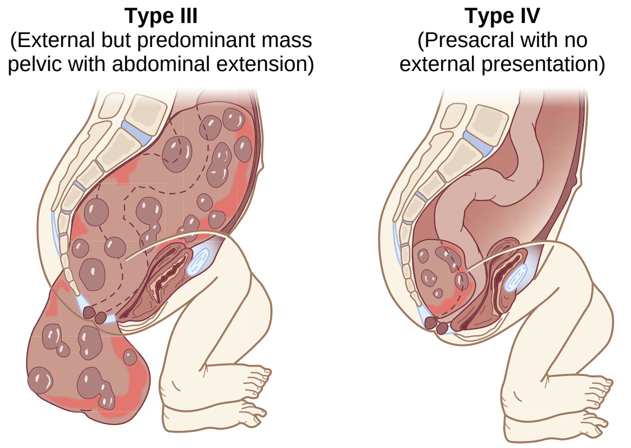
Fetuses diagnosed with SCT before 30 weeks gestation or with rapidly growing tumors have a poor prognosis (<7% survival), but may benefit from in utero intervention.[203] Radiofrequency ablation, embolization, thermocoagulation of the tumor or vascular supply, and cyst drainage have been employed to treat SCT in utero and prevent hydrops fetalis, but the benefit remains unclear.[127,203]

A review of minimally invasive fetal intervention for SCT in 34 patients from 1980 to 2013 demonstrated an overall survival rate of 44% with mean delivery at 29.7 ± 4.0 weeks.[199] Preexisting hydrops led to a worse outcome, with only 30% survival (6/20) in this cohort. A subsequent review of 33 patients examined the effectiveness of different techniques, comparing interstitial tumor ablation (n = 22) to targeting the feeding vessels of the tumor (n = 11).[127] Fetuses undergoing vascular ablation seemed to have a survival advantage over the interstitial ablation group (63.6% vs. 40.9%), which the authors suggested may be because interstitial ablation often led to tumor necrosis and subsequent hemorrhage.



Type I
(Predominantly external with only a minimal presacral component)

Type II
(Presenting externally but significant intrapelvis extension)



Type III
(External but predominant mass pelvic with abdominal extension)

Type IV
(Presacral with no external presentation)

Fig. 63.9 Sacrococcygeal tumors are classified according to their location. Type I tumors are predominantly external (sacrococcygeal) with minimal presacral component; type II tumors present externally but have a significant intrapelvic extension; type III tumors are present externally but the predominant mass is pelvic and extends into the abdomen; type IV tumors are presacral with no external presentation. (Redrawn from Altman RP, Randolph JG, Lilly JR. Sacrococcygeal teratoma: American Academy of Pediatrics Surgical Section Survey-1973. *J Pediatr Surg*. 1974;9:389–398.)

SCTs have been resected in utero (Fig. 63.10) with successful outcomes, but the optimal timing and criteria for fetal intervention is uncertain.[12,198,199,204] Fetal teratoma resection has a high risk for fetal hemorrhage; consequently, intraoperative placement of a venous catheter in a fetal hand, leg, or umbilical cord vein is important for the ability to transfuse compatible blood and crystalloid or rapidly administer resuscitation drugs.

In certain cases, fetal SCT may lead to maternal mirror syndrome, in which maternal physiology mimics the abnormal circulatory physiology of the hydropic fetus.[205] The mother develops hypertension with increased peripheral and pulmonary edema from a hyperdynamic state. Mirror syndrome is a form of severe preeclampsia that may develop in association with fetal hydrops and in most cases necessitates delivery,[206] although platelet levels and liver enzymes typically remain in normal ranges. Maternal mirror syndrome does not normally resolve immediately with correction of the fetal pathophysiology and can result in life-threatening maternal complications.[205,207]

CCAM, Congenital cystic adenomatoid malformation.

Modified from tables in David M, Lamas-Pinheiro P, Henriques-Coelho T. Prenatal and postnatal management of congenital pulmonary airway malformation. *Neonatology* 2016;110:101–115; and Fowler DJ, Gould SJ. The pathology of congenital lung lesions. *Semin Pediat Surg*. 2015;24:176–182.

CONGENITAL PULMONARY LESIONS

Congenital pulmonary airway malformations (CPAMs), historically known as congenital cystic adenomatoid malformations, are typically benign nonfunctioning pulmonary tumors composed of cystic and solid components normally contained within a single lung lobe.[208] These fetal lesions complicate approximately 1 in 25,000 to 35,000 live births.[209] Other possible fetal abnormalities that require differentiation include bronchopulmonary sequestration, bronchogenic cysts, congenital lobar emphysema, neurogenic cysts, peripheral bronchial atresia, and CDH.[210] CPAM includes five subtypes (Table 63.5) that are based on the presumed tumor development site.[211] Prenatal ultrasonography categorizes lesions as macrocystic (cysts > 5 mm in diameter) or microcystic (cysts < 5 mm in diameter), with microcystic lesions having a more solid or echogenic image.[212] Typically, small lesions regress in the third trimester and can be surgically resected after birth or managed conservatively without surgical intervention.[213] Large lesions can compress the great vessels, create pulmonary hypoplasia, and cause cardiac compression and mediastinal shift that often results in hydrops fetalis. Prognosis depends primarily on size and growth characteristics of the CPAM rather than lesion type.[214] To normalize tumor volume to fetal size, ultrasound measurement of CPAM volume to fetal head circumference ratio (CVR) was evaluated as a predictor of hydrops fetalis and other postnatal outcomes.[214-216] CVR is calculated from the volume of an ellipse using the formula (length × height × width × 0.52)(cm^3)/fetal head circumference (cm).[217] Based on retrospective data from 71 fetuses, a CVR less than 0.56 predicts no adverse postnatal outcome (100% negative predictive value), whereas a CVR greater than 0.56 had a positive predictive value for adverse postnatal outcome of 33%.[215] In addition, a CVR greater than 1.6 is associated with greater risk for hydrops fetalis.[214-216] A recent retrospective analysis of a series of 24 fetuses with a CVR greater than 1.6 found that an abnormal echocardiogram with hydrops was a significant predictor of mortality and need for fetal intervention.[218]

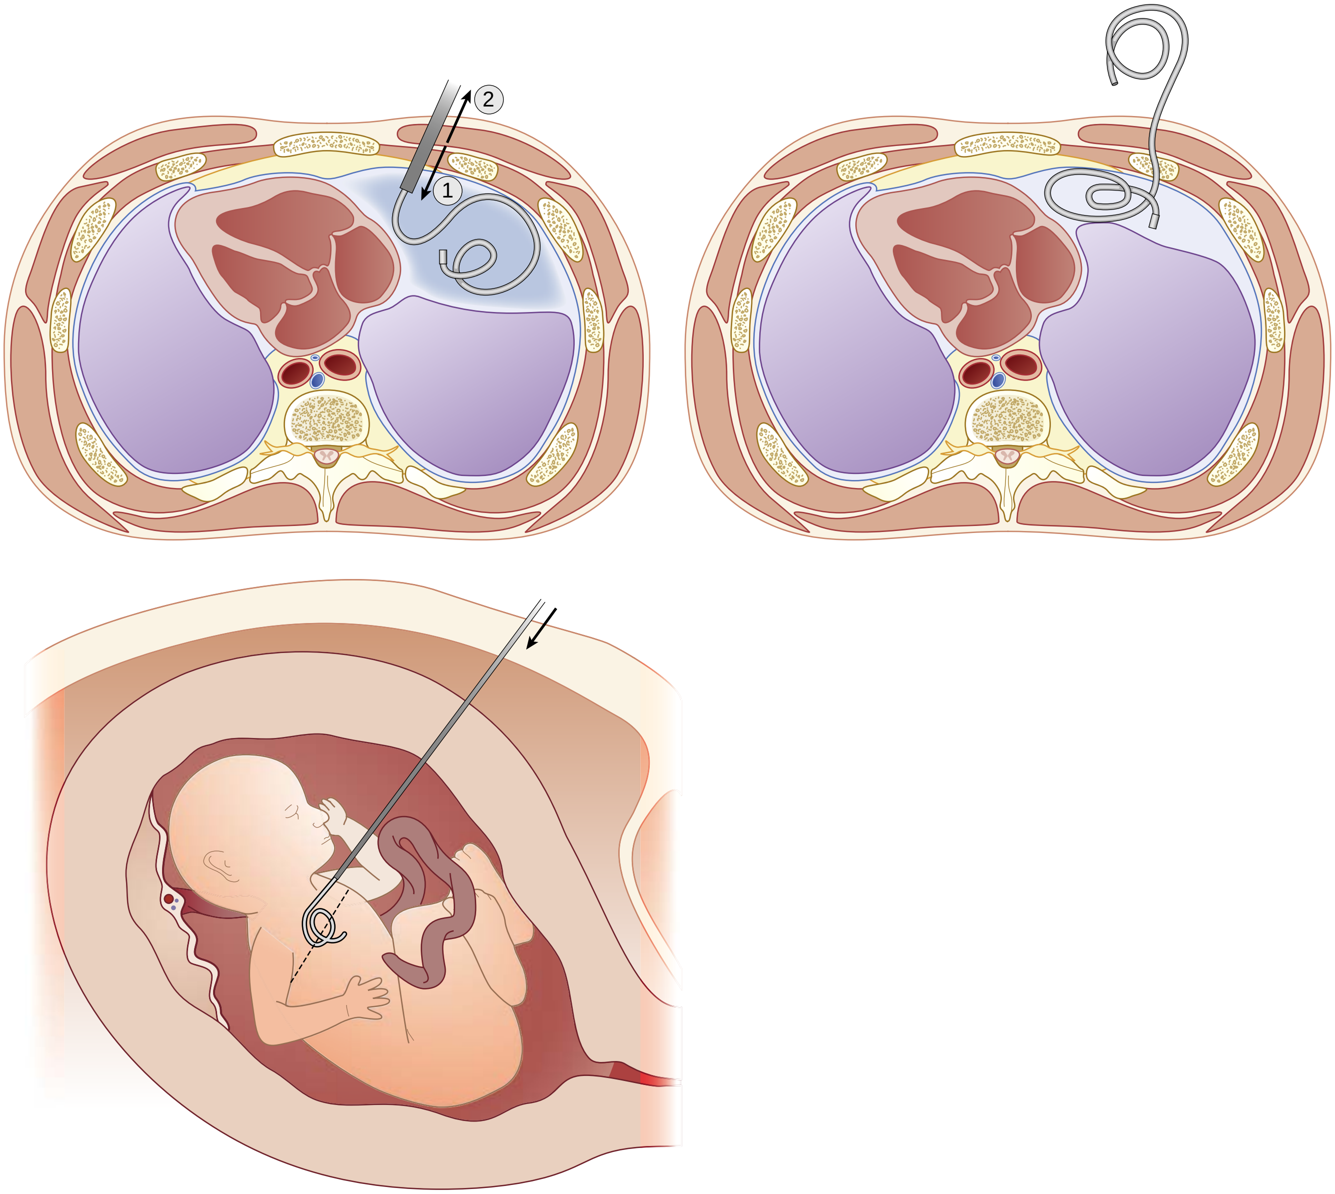

Fig. 63.11 Thoracic shunt insertion (*top left* and *right*) and deployment *(bottom left)*. (From van Mieghem T, Baud D, Devlieger R, et al. Minimally invasive fetal therapy. *Best Pract Res Clin Obstet Gynaecol.* 2012;26:711–725.)

Some lesions regress and leave minimal impact, whereas others grow in size. Patients with CPAM tumors associated with hydrops fetalis have a survival rate of less than 5% without intervention, and early delivery or fetal treatment is indicated in these cases.[219,220] Administration of maternal betamethasone may improve survival in patients with high-risk CPAM.[220,221] Large macrocystic lesions or large pleural effusions can be decompressed in utero by placement of shunt catheters between the cysts and the amniotic cavity (Fig. 63.11). Use of fetal analgesics and muscle relaxants delivered intramuscularly with ultrasound guidance may decrease the fetal stress response and prevent fetal movement during critical portions of the procedure. Shunt placement can prevent or reverse hydrops formation, with definitive resection deferred until after birth.[222] In a retrospective analysis of 75 fetuses undergoing shunt placement for pleural effusion or a macrocystic lung lesion,[223] shunt placement resulted in a decrease in macrocystic lung lesion volume by 55 ± 21% and complete or partial resolution of the pleural effusion in 29% and 71% of fetuses respectively. Hydrops resolved in 83% of fetuses following intervention. Overall neonatal survival was 68%, and correlated with hydrops resolution, GA at birth, a unilateral pleural effusion, and percent reduction in lesion size.[223] Another retrospective study noted a 59% survival rate for fetuses with hydrothorax treated with thoracoamniotic shunts, though repeat procedures were often necessary.[224] In some CPAM lesions, shunts are ineffective because cysts are not in communication with each other, shunts malfunction, or they become displaced. In addition, shunt placement can cause fetal hemorrhage, preterm PROM, or chorioamnionitis.[210] Thoracoamniotic shunt placement has also successfully decompressed large congenital pleural effusions caused by fetal chylothorax that otherwise would result in hydrops fetalis, pulmonary compression, and fetal or neonatal death.[225,226]

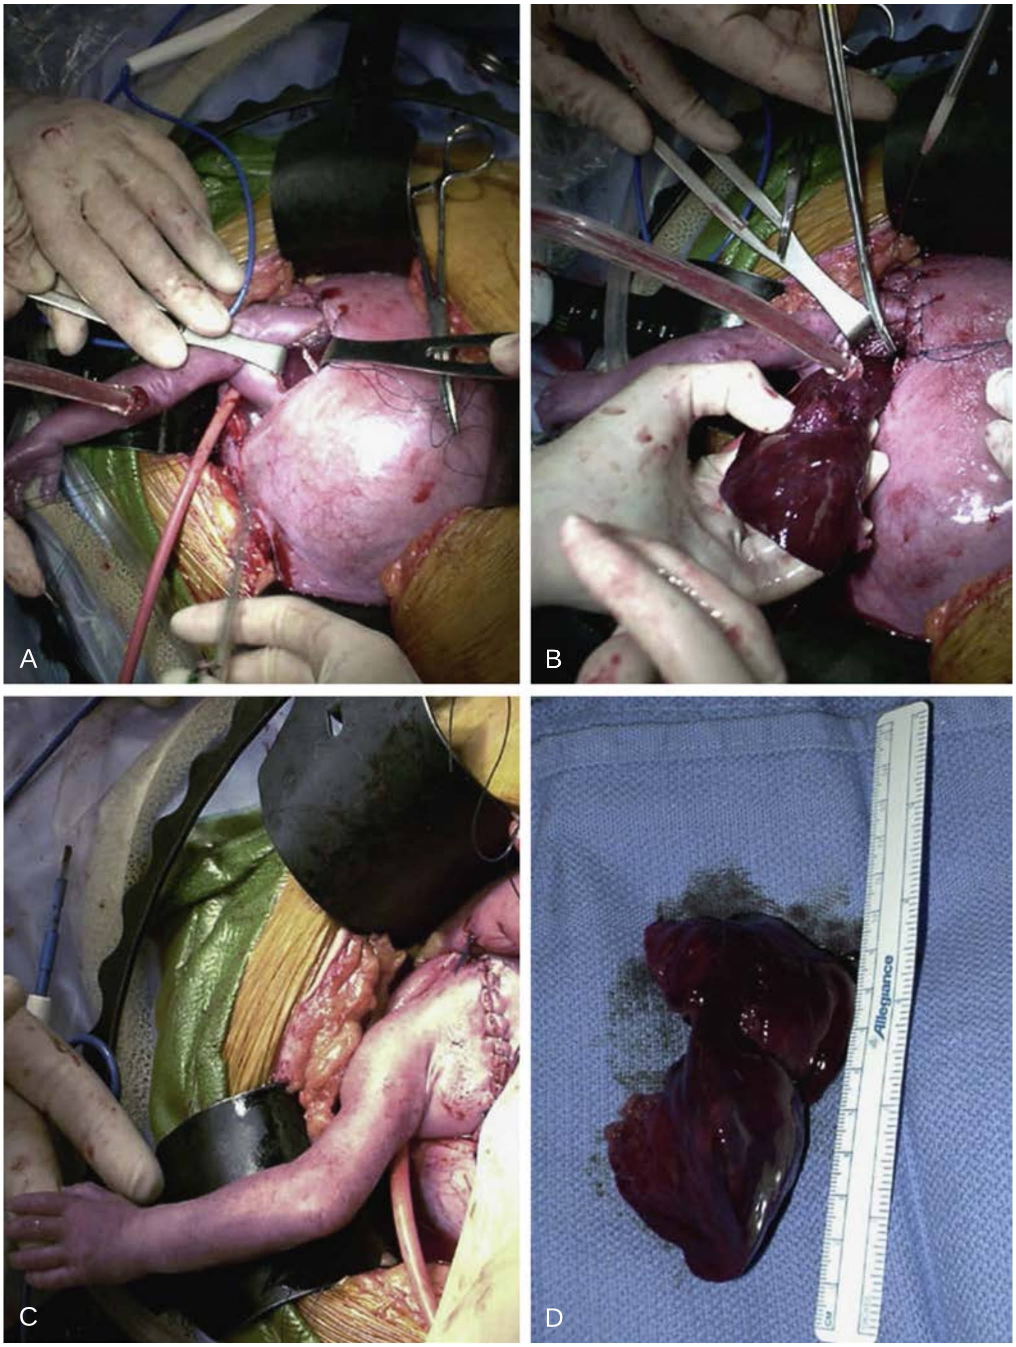

Fig. 63.12 (A) Open resection of fetal congenital pulmonary airway malformation (CPAM) with fetal thoracotomy shown. (B) Resected CPAM mass. (C) Primary closure of fetal thoracotomy. (D) Pathologic specimen of resected CPAM mass. (Courtesy Dr. Anita Moon-Grady, University of California, San Francisco Fetal Treatment Center, San Francisco, CA.)

Some solid or mixed solid/cystic CPAMs inappropriate for shunting can be resected with open fetal lobectomy (Fig. 63.12). Similar to open SCT resection, potential exists for significant fetal hemorrhage and need for in utero fetal resuscitation. Open resection of CPAM lesions associated with hydrops fetalis has resulted in a 30-day postnatal survival rate of 50% to 60%, with tumor resection allowing for compensatory lung growth and resolution of hydrops fetalis.[227]

In some instances, use of an EXIT procedure with fetal thoracotomy, mass resection, and a secured airway before delivery has been a successful approach for tumors with persistent mediastinal compression.[228,229] In a series of nine fetuses with large lung masses (CVR 1.9-3.6 at term) who underwent an EXIT-to-resection procedure, all procedures were successful, with no significant operative complications.[228]

Preoperative Assessment and Counseling

Many considerations for perioperative management of women undergoing maternal-fetal surgery are analogous to those for nonobstetric surgery during pregnancy. Maternal safety is the primary focus when determining a plan that will optimize fetal outcome. All members of the multidisciplinary team should be actively involved in maternal counseling, patient assessment, and perioperative planning. Optimum functioning of a fetal treatment program requires effective communication among the members of a multidisciplinary team, including surgeons, ultrasonographers, maternal fetal medicine physicians, anesthesiologists, nurses, genetic counselors, and social workers. Regularly scheduled multidisciplinary care meetings help ensure coordination of a complete and appropriate perioperative plan, ensure availability of the necessary equipment and personnel at the time of the procedure, and maximize the chance for optimal outcomes for both the mother and fetus. Participation of the anesthesiologist is critical for preoperative maternal assessment to determine whether maternal risk is acceptably low for potential fetal benefit. An understanding of the physiologic changes of pregnancy (for details, see Chapter 62) and their effects on anesthetic management is necessary for appropriate perioperative planning and risk assessment.

Maternal counseling regarding risks and benefits of the procedure should be thorough, unbiased, and convey the most recent outcome and complication data about the planned intervention. For nonurgent procedures, counseling is typically a multi-day process. The team must review the specific condition's natural history, diagnostic limitations, and whether associated anomalies are detected.[230] Discussions should focus on specific implications to the mother, the pregnancy, the fetus, postnatal care, future pregnancies, intermediate and long-term outcomes, and possible adverse outcomes.[6] Patient discussions also should include alternative options such as nonintervention or pregnancy termination if applicable. To provide uniform counseling, all providers should advise the patient regarding information specific to their discipline, but be aware of the general risks and benefits of the fetal process and the proposed procedure (see prior section on "Indications, Procedures, and Outcomes"). Distinctions should be made between interventions that are evidence based, and those that are innovative or experimental. Mothers should be informed about the planned timing and method of delivery, future reproductive implications, and the risk for uterine rupture and need for cesarean delivery with this and all future pregnancies if a hysterotomy is planned. Fertility does not appear to be affected by open fetal surgery, but the risk for uterine rupture or dehiscence before delivery is significant and comparable or even greater than that associated with a prior cesarean delivery performed with a classic incision.[231]

In some situations, consultation with a palliative care provider, clergy, or ethicist may be helpful. In addition, the sequence of events should be outlined in detail so that all questions can be answered. In most circumstances, it is important that the partner or other supporting individuals be included in the counseling process to ensure they have an understanding of the rationale behind the treatment decisions. However, the wishes of the mother assume ultimate priority during pregnancy. Thorough counseling regarding fetuses with pediatric surgical disorders reduces parental anxiety.[232,233] Most mothers prefer specific realistic information provided in an empathetic manner, no matter how dire, and want to be allowed to hope for the best possible outcome.[234] If the fetus is of viable GA, additional counseling is required about the mother's wishes for possible emergent delivery and neonatal resuscitation in the event of unplanned fetal distress unresponsive to in utero treatment. Finally, the fetal intervention should not proceed until the patient has had adequate time to carefully consider all the information and given informed consent.

Intraoperative Management and Considerations

Unlike most surgical procedures performed during pregnancy in which the fetus is merely a bystander (e.g., maternal appendectomy), fetal surgery involves two surgical patients. Consequently, in addition to maternal considerations for anesthetic administration during pregnancy, it is essential to understand the impact of surgery and anesthetic administration on fetal physiology, methods for fetal analgesia and anesthesia, techniques for fetal monitoring, intraoperative anesthetic management, and postoperative care for both mother and fetus.

FETAL PHYSIOLOGY AND MONITORING

During fetal surgery, procedural and pharmacologic interventions can adversely affect fetal physiology by altering uteroplacental or fetoplacental circulation and gas exchange. Appropriate fetal monitoring facilitates early intervention. In addition to the physiologic effects of medications administered to the mother or fetus, a detailed knowledge of both maternal physiology of pregnancy, and fetal cardiovascular, neurologic, and placental physiology provides the basis for optimal fetal care. Uteroplacental and fetoplacental physiology, including uterine perfusion, placental gas exchange, and drug transfer are detailed in Chapter 62, which also discusses the effects of maternal positioning, maternal neuraxial anesthesia, and administration of general anesthesia on the uteroplacental unit.

Fetal cardiac output depends primarily on heart rate.[235] Compared to a neonate, the contractility of the fetal myocardium is decreased secondary to decreased myofibrillar density and it is intolerant of hypocalcemia because of an immature calcium regulatory system.[236] Fetal myocardium is also less compliant than adult myocardium, near the peak of the Frank–Starling ventricular function curve, and fluid-filled lungs also inhibit additional ventricular filling.[236,237] Consequently, modest changes in preload have minimal effect on cardiac output. The normal fetal cardiac output (sum of right and left ventricular output) is in the range of 425 to 550 mL/min/kg throughout gestation.[235]

Fetal blood volume increases during gestation, and approximately twothirds of the fetal-placental blood volume resides within the placenta and the placenta receives about 40% of the fetal cardiac output.[238,239] During the second trimester, fetal blood volume is estimated to be approximately 110 to 160 mL/kg of fetal body weight.[240] After midgestation, fetal blood volume can be estimated based on GA using the equation, estimated fetal blood volume (mL) = 11.2 × GA – 209.4.[241] In the developing fetus, hemoglobin F is the

primary oxygen carrier. Beginning at 32 weeks' gestation there is a gradual shift toward adult hemoglobin synthesis.[242] Mean fetal Hb levels increase linearly from 11 g/dL at 17 weeks gestation to 18 g/dL in a term neonate.[243,244]

Fetal lung epithelium produces more than 100 mL/kg/day of fluid that fills the lungs and facilitates appropriate pulmonary growth and development. Excess lung fluid exits the trachea and is either swallowed or flows into the amniotic fluid. Although fetal hepatic enzymes are less functional than those of adults, most drugs still undergo metabolism and the umbilical circulation provides initial hepatic metabolism (first-pass metabolism) before medications reach the fetal brain or heart. Although fetal liver function is immature, coagulation factors are synthesized independent of the maternal circulation and do not cross the placenta. The serum concentrations of these factors increase with GA (Table 63.6),[245] but fetal clot formation in response to tissue injury is decreased in contrast to that in adults throughout gestation and the first 6 months of life.[246] Platelets first appear at 5 weeks gestation and increase in number with time, reaching a mean of 150×10^9/L by the end of the first trimester of pregnancy and values reaching normal adult range by 22 weeks gestation.[247]

During open procedures, the fetal circulation and flow distribution can be severely impaired by fetal manipulation or direct compression of the umbilical cord, inferior vena cava, or mediastinum. Increased uterine activity, maternal hypotension, and significant maternal hypocarbia can all decrease uteroplacental perfusion. Fetal heart rate (FHR) monitoring is important during both minimally invasive and open procedures. During IUT, the transfusion needle can lacerate umbilical vessels with unanticipated fetal movement, and use of laser therapy for TTTS can disrupt surface placental vessels critical to fetal blood flow. During labor, FHR monitoring with external Doppler or a fetal scalp electrode is commonly employed to assess fetal well-being, but during fetal procedures, echocardiography, pulse oximetry, and ultrasound imaging of umbilical artery flow are the primary methods for fetal assessment. After exposure of the fetal head during an EXIT procedure, placement of an Hb saturation monitor and insertion of a fetal scalp electrode have both been used successfully for FHR monitoring.[11,248] It remains unclear whether fetal oximetry or heart rate monitoring is more sensitive to decreased umbilical-fetal blood flow. In a fetal lamb model examining the effects of umbilical cord compression, Hb desaturation was detected by fetal pulse oximetry before the onset of bradycardia.[249] However, FHR deceleration has been shown to precede fetal Hb desaturation with use of fetal pulse oximetry monitoring during labor.[250]

Intraoperative ultrasonography allows imaging of FHR, cardiac contractility, and cardiac filling, as well as Doppler assessment of flow in the ductus arteriosus and umbilical artery flow. Both absent and reversed umbilical artery diastolic flow are associated with increased perinatal morbidity and mortality.[251] In many cases, ultrasonography assessment of fetal well-being can be only intermittent. This is because ultrasonography may be periodically required to guide the intervention or the probe placement can interfere with the surgical procedure.

When intraoperative monitoring detects depression of fetal hemodynamics, steps should promptly be undertaken to improve uterine perfusion, ensure the uteroplacental interface is intact, and relieve any compression of the umbilical cord or placenta. These steps may include administration of medications to increase maternal blood pressure, cardiac output, and uterine relaxation. In some cases, administration of resuscitation medications directly to the fetus may be needed, or if previously determined to be viable ex utero fetal resuscitation may be necessary.

In utero, the fetus is unable to thermoregulate and depends on maternal body temperature secondary to placental circulation and surrounding amniotic fluid. Induction of general anesthesia, surgical exposure, and hysterotomy can reduce fetal temperature dramatically both directly and secondarily if maternal core temperature drops significantly. Fetal sheep studies demonstrate the fetus is unable to generate heat through thermogenesis[252] and decreases in sheep fetal temperature can lead to tachycardia and hypertension in utero. In contrast, human reports associate maternal/fetal hypothermia with fetal bradycardia.[253,254] Consequently, maintenance of maternal euthermia with use of forced air warming likely improves fetal well-being during minimally invasive procedures. During open fetal surgery, use of warmed fluid for intrauterine irrigation and monitoring of both maternal core and amniotic fluid temperatures are also important.

FETAL ANESTHESIA, ANALGESIA, AND PAIN PERCEPTION

The capability of the fetus to perceive pain remains controversial. The fetus exhibits pituitary-adrenal, sympathoadrenal, and circulatory stress responses to noxious stimuli as early as 16 to 18 weeks gestation.[255-258] Although invasive fetal procedures elicit a stress response,[30,259,260] this response is mediated at the level of the spinal cord, brainstem, and/or basal ganglia and does not necessarily correlate with conscious cortical perception of pain.[261] Administration of opioids in preterm neonates blunts hormonal responses to surgery, including changes in plasma adrenaline, noradrenaline, glucagon, aldosterone, corticosterone, glucose, and lactate.[262] Providing adequate anesthesia and analgesia is associated with both attenuation of the deleterious effects and improved outcomes.[259] Stress responses secondary to invasive fetal procedures are blunted with opioid administration,[30] but reduction of plasma stress hormone levels is not necessarily evidence of adequate analgesia.[261]

Pressure, temperature, and vibration sensory nerve terminals develop in human skin between 6 and 10 weeks gestation.[263] Skin nerve terminals required for peripheral sensory nociception likely develop between 10 and 17 weeks gestation.[264] Noxious stimuli follow a reflex arc of afferent fibers that synapse on spinal cord interneurons, which then synapse with motor neurons. A fetus can reflexively withdraw from a noxious stimulus by 19 weeks GA without input from the cerebral cortex.[265,266]

The perception of pain requires not only intact neural pathways from the periphery to the primary sensory cortex, but also higher cortical structures.[266] Thalamocortical circuits, thalamic pain fibers likely reach the somatosensory cortex at 24 to 30 weeks gestation.[258,266] Thalamic projections reach the visual subplate at 20 to 22 weeks,[267] the visual cortex at 23 to 27 weeks,[268] and the auditory cortical plate at about 26 to 28 weeks gestation.[269] However, fetuses are unlikely to experience pain before 24 weeks gestation because the cortex requires additional growth, remodeling, and development to establish the extensive neural network of pathways to other central nervous system structures.

This timeline is supported by electroencephalographic (EEG) studies. Cortical EEG activity is present only 2% of the time in fetuses at 24 weeks gestation and increases to being present 80% of the time with EEG patterns becoming more distinct by 34 weeks gestation.[270]

Both the long-term impact of untreated fetal stress and the timing of fetal pain perception remain unknown. Given this uncertainty and the more than 35-year history of safe anesthetic administration in neonates and fetuses undergoing invasive procedures,[271-273] analgesia should be provided during fetal surgery.[258,274] In addition to blunting pain, administration of fetal analgesia helps to prevent fetal movement and inhibit the circulatory stress response.

Opioid analgesics can be transferred to the fetus by maternal administration or direct fetal intramuscular or intravenous umbilical cord administration using ultrasound guidance. For most invasive procedures causing noxious fetal stimulation, fetal intramuscular administration of fentanyl 10 to 20 μg/kg (or other opioid in equivalent dosing) is used to provide analgesia immediately before the intervention.[30,183,258] This can be achieved percutaneously using ultrasound guidance or under direct vision when a hysterotomy is performed. Some physicians administer prophylactic intramuscular atropine 20 μg/kg with opioids to minimize the risk for fetal bradycardia.[275,276] Fetal movement can be prevented by intramuscular or umbilical vessel administration of a muscle relaxant such as rocuronium (intramuscular 2.5 mg/kg or intravenous 1.0 mg/kg) or vecuronium (intramuscular 0.25 mg/kg or intravenous 0.1 mg/kg) using ultrasound guidance.[183,258] The onset of fetal paralysis varies with the specific drug and dose, but typically occurs in 2 to 5 minutes, with an approximate duration of 1 to 2 hours.[277] In many instances, opioid, anticholinergic, and muscle relaxant are combined in a single injection. Maternal administration and placental transfer of intravenous remifentanil provides adequate fetal immobility during fetoscopic interventions that involve only the umbilical cord or placenta.[278]

For open fetal procedures, placental transfer of maternally administered general anesthesia with volatile anesthetics provides fetal anesthesia. These anesthetics readily transfer across the placenta, with fetal concentration and the fetal-to-maternal (F/M) ratio depending on both the maternal inspired anesthetic concentration and the duration of maternal anesthetic administration. In human studies of anesthetic levels at the time of cesarean delivery (~10-minute duration of general anesthesia), isoflurane has an F/M ratio of approximately 0.7.[279] Although placental transfer of desflurane and sevoflurane may be similar, published human F/M data are not currently available in the literature. Nitrous oxide has an F/M ratio of 0.83 after only 3 minutes of administration.[280]

High levels of volatile anesthetic can depress fetal myocardium and lead to increasing fetal acidosis.[281] In animal models, volatile anesthetic concentrations often employed for uterine relaxation (>2 minimum alveolar concentration [MAC]) lead to significant reductions in maternal cardiac output with associated decrease in uterine perfusion up to 30%.[282] A retrospective analysis of echocardiographic data from clinical cases of open fetal surgery and EXIT procedures reveals a moderate-to-severe left ventricular systolic fetal cardiac dysfunction with use of high concentrations of desflurane.[283] In addition, case reports have described epileptiform EEG activity and generalized tonic-clonic seizures in both adults and children exposed to high levels of sevoflurane.[284] Seizure activity has also been attributed to high-dose sevoflurane during an open fetal procedure.[285] Therefore, high concentrations of volatile anesthetic administration, while useful for maternal uterine relaxation, may not be the optimal anesthetic for the fetus despite years of successful use. Consequently, a reduced level of volatile anesthetic (1.0-1.5 MAC) is combined with remifentanil and propofol infusions for open fetal surgery at some institutions.[283,286] Remifentanil has significant placental transfer and prevents fetal movement during TTTS laser photocoagulation therapy.[278,287] Some prefer to administer maternal remifentanil and nitroglycerin as part of the anesthetic for open fetal or EXIT procedures to decrease the amount of volatile anesthetic.[275,278,288] Currently, no evidence indicates that any one anesthetic method provides an improved fetal or maternal outcome as long as appropriate uterine quiescence is maintained.

Anesthetic neurotoxicity of the developing brain is a concern for all providers administering anesthetic agents for fetal procedures. In animal models, anesthetics affect neonatal brain development and create histologic changes, as well as learning and memory deficits.[289,290] Recent nonhuman primate studies found repeated exposures to clinically-relevant concentrations of sevoflurane during infancy resulted in neurocognitive impairment and behavioral changes at 1 to 2 years of age.[291,292] However, specific long-term effects of anesthetics on human brain function in neonates or fetuses are currently inconclusive. Two prospective trials examining the effect of a short anesthetic exposure have suggested no long-term neurodevelopmental consequences.[293-295] In 2016, the U.S. Food and Drug Administration advisory committee issued a warning that "repeated or lengthy use of general anesthetic and sedation drugs during surgeries or procedures in children younger than 3 years or in pregnant women during their third trimester may affect the development of children's brains."[296]

Limited data about anesthetic exposure in the fetal population exists. One study looked retrospectively at the use of general anesthesia for cesarean section and the incidence of learning disabilities at age 5 and found no correlation.[297] To date, no studies have examined the neurocognitive consequences of midgestation fetal anesthesia. No general anesthetic agent is known to be superior to another, and whether exposure to general anesthetics during gestation compared to the neonatal period is more beneficial or harmful is unknown. In an effort to systematically collect current data, an international registry has been established for the purpose of assessing the long-term neurodevelopmental outcomes of fetal surgery patients (Clinical Trials.gov identifier NCT02591745).[298] In addition, whether in utero exposure to anesthetic drugs compared with postnatal exposure has any effect on neurocognitive outcome is not known and makes data collection and analysis challenging, as many patients undergoing fetal procedures are re-exposed to general anesthesia during infancy and childhood.[299]

MANAGEMENT OF MINIMALLY INVASIVE PROCEDURES

The same considerations that apply to nonobstetric surgery during pregnancy should be followed for fetal procedures. For most fetal image-guided surgery procedures (see Table 63.1), use of monitored anesthetic care with local anesthesia infiltration into the superficial tissues and abdominal wall provides an adequate level of maternal comfort. Administration of additional opioid, benzodiazepine, or other anesthetic agent can be used for maternal analgesia and anxiolysis. Use of supplemental anesthetic drugs will also decrease the likelihood of fetal movement via placental transfer. Local anesthetic infiltration can also be used for fetoscopic procedures, which typically employ endoscope trocars that are only 2 to 5 mm in diameter.[300] Neuraxial techniques can be beneficial and preferable when multiple insertion sites are required; maternal immobility must be ensured; a mini-laparotomy must be performed; or concern exists about adequate patient comfort or cooperation during the procedure. General anesthesia is rarely necessary for percutaneous procedures unless placental location and fetal orientation present potential technical difficulty or uterine exteriorization is needed, as is the case with fetoscopic MMC repair.[301]

Although maternal intravenous fluid administration should be guided by standard intraoperative requirements, use of significant amounts of pressurized uterine crystalloid irrigation into the amniotic cavity during fetoscopic surgery should be avoided because it has resulted in maternal pulmonary edema.[302]

In cases of IUT, cord blood sampling, or thoracic shunt placement, fetal movement may displace the needle or catheter and result in trauma, bleeding, or compromise of the umbilical circulation. In one study of fetoscopic surgery, maternal administration of remifentanil (0.1 μg/kg/min) reduced fetal movement and improved operating conditions compared with maternal administration of diazepam.[278] Although maternally administered opioids and benzodiazepines can reduce fetal motion,[123] they do not guarantee immobility for procedures directly involving the fetus. Fetal immobility can be safely achieved with direct fetal intramuscular or umbilical venous administration of muscle relaxant. For invasive fetal procedures that involve potentially noxious stimulation to the fetus, such as shunt placement, endoscopic MMC repair, or fetal cardiac interventions, an opioid should be administered to the fetus (e.g., intramuscular fentanyl 10-20 μg/kg). When general anesthesia is employed, placental transfer of a volatile anesthetic provides significant fetal anesthesia and decreases fetal movement, but supplemental opioids should also be administered if fetal analgesia is required.

Weight-based unit doses of atropine (20 μg/kg) and epinephrine (10 μg/kg) should be immediately available in individually labeled syringes for direct fetal administration by the surgeon under ultrasonography guidance. These medications require sterile transfer to the surgical field preoperatively, meticulous labeling, and accurate dosing before commencement of the procedure. The surgeon can administer the indicated medication by a variety of routes (intramuscular, intravenous, or intracardiac) depending on the procedure and urgency of the situation. If gestational development is compatible with extrauterine life, the obstetric team should be prepared to perform an emergency cesarean delivery if fetal bradycardia persists despite efforts to resuscitate in utero. The anesthesiologist should be prepared to emergently provide maternal general anesthesia and assist with neonatal resuscitation.

MANAGEMENT OF OPEN PROCEDURES

Although most women undergo cesarean delivery with neuraxial anesthesia, general anesthesia is primarily employed for fetal surgery requiring a hysterotomy. Unlike minimally invasive fetal procedures, open fetal surgery requires profound uterine relaxation and often entails additional fetal monitoring beyond intermittent ultrasonography. Open surgery involves more surgical stimulation, hemodynamic perturbation, and risk for fetal compromise and requires direct administration of drugs to the fetus. Compared to minimally invasive procedures, open fetal procedures present greater risk to the mother. The anesthesiologist and other team members should be prepared for significant maternal and fetal blood loss, the need for maternal and fetal resuscitation, and possible emergent delivery. A volatile anesthetic is commonly administered to provide maternal and fetal anesthesia, as well as uterine relaxation, which may require a concentration of more than 2 MAC.[303] In an effort to decrease the fetal cardiac dysfunction and abnormal umbilical artery flow associated with high levels of volatile anesthetics, more recent techniques combine 1

BOX 63.2 Perioperative Considerations for Open Fetal Surgery*

Preoperative

- Complete maternal history and physical examination
- Complete fetal workup to exclude other anomalies
- Imaging studies to determine fetal lesion and placental location and estimated weight
- Maternal counseling by multidisciplinary team and presurgical team meeting
- Planning for emergent delivery depending on viability
- High lumbar epidural placement for postoperative analgesia with test dose before use
- Prophylactic premedications: nonparticulate antacid (aspiration) and rectal indomethacin (tocolysis)
- Blood products typed and crossmatched for potential maternal and fetal transfusion; fetal blood should be type O-negative, leukocyte depleted, irradiated, cytomegalovirus negative, and crossmatched against the mother
- Transfer of weight-based fetal resuscitation drugs to scrub nurse in unit doses
- Sequential compression devices on lower extremities for thrombosis prophylaxis
- Initiation of forced air warmer to maintain maternal normothermia following induction

Intraoperative

- Left uterine displacement and standard monitors
- Fetal assessment prior to maternal induction
- Preoxygenation for 3 min before induction
- Rapid sequence induction and intubation
- Maintain maternal FiO_2 greater than 50% and end-tidal carbon dioxide 28-32 mm Hg
- Ultrasonography examination to determine fetal position and placental location
- Urinary catheter placed; additional large-bore intravenous access obtained; possible arterial line
- Prophylactic antibiotics administered
- Maternal blood pressure maintained with IV phenylephrine, ephedrine, and/or glycopyrrolate; typical goal is to maintain mean arterial pressure within 10% of preinduction baseline with appropriate heart rate
- After skin incision, increased concentrations of volatile anesthetic (2-3 MAC) started to obtain uterine relaxation; alternatively, volatile anesthetic (1.0-1.5 MAC) may be combined with IV propofol and remifentanil
- Consider increasing vapor or adding IV nitroglycerin if uterine tone remains increased
- Placement of fetal monitors if needed (e.g., fetal pulse oximeter, intrauterine temperature probe)
- IM fetal administration of opioid and neuromuscular blocking agent; an anticholinergic also may be administered with the opioid
- Placement of fetal IV access device if significant fetal blood loss anticipated
- External irrigation of fetus with warmed saline as needed
- Crystalloid restriction to less than 2 L to reduce risk for maternal pulmonary edema; consider colloid administration
- IV loading dose of magnesium sulfate once uterine closure begins
- Discontinue volatile agents once magnesium sulfate load is complete
- Activate epidural for postoperative analgesia
- Administer maternal anesthetics as needed
- Monitor maternal neuromuscular blockade carefully because of possible prolongation from magnesium sulfate
- Extubate trachea when patient is fully awake

Early Postoperative Considerations

- Complete postoperative debrief
- Continue tocolytic therapy
- Patient-controlled epidural analgesia
- Monitor uterine activity and fetal heart rate
- Ongoing periodic fetal evaluation

*This summary may need to be modified depending on the type of open fetal surgery and patient comorbidities.

FiO_2, Fraction of inspired oxygen; *IM,* Intramuscular; *IV,* Intravenous; *MAC,* Minimum alveolar concentration.

Modified from Ferschl M, Ball R, Lee H, et al. Anesthesia for in utero repair of myelomeningocele. *Anesthesiology.* 2013;118:1211–1223.

to 1.5 MAC of volatile anesthetic with infusions of remifentanil and propofol.[283,286,304] The perioperative considerations for open fetal surgery are detailed in Box 63.2.

Weight-based unit doses of medications for fetal analgesia and muscle relaxation as previously detailed in the section on “Fetal Anesthesia, Analgesia, and Pain Perception” should be available for administration by the surgical team. In addition, resuscitation medications (atropine 20 μg/kg, epinephrine 10 μg/kg, and crystalloid 10 mL/kg) should be prepared preoperatively in sterile weight-based unit doses for emergent treatment of intraoperative fetal hemodynamic compromise. Crossmatched blood should be available for maternal transfusion. For procedures with a high risk of fetal hemorrhage, appropriate blood for fetal transfusion (i.e., O-negative, cytomegalovirus-negative, irradiated, leukocyte-depleted, maternally crossmatched) should be readily available.

Uterine tocolytics (i.e., indomethacin) should be administered to the mother preoperatively. An epidural catheter is placed preoperatively for administration of postoperative analgesia. FHR is assessed and baseline cardiac echocardiography and ultrasound imaging of umbilical cord flow characteristics are performed before anesthetic induction and are intermittently reevaluated throughout the initial period of anesthetic administration to assess the effect of the maternal positioning, anesthetic administration, and any maternal hemodynamic changes on the fetus. Absent or reversed umbilical artery diastolic flow intraoperatively may be an early sign of fetal distress.[304] Additional monitoring sites include fetal cardiac systolic function and flow across the ductus arteriosus.[283,305,306] The gravid uterus is displaced leftward and general anesthesia is induced with a rapid sequence technique identical to patients undergoing nonobstetric surgery during pregnancy.

After anesthetic induction and before maternal skin incision, conventional concentrations of anesthetics are administered to the mother. Ventilation is controlled to maintain eucapnia (end-tidal carbon dioxide levels of 28-32 mm Hg). Fetal condition and fetal and placental locations are reassessed by ultrasound. If an intraarterial catheter is not placed, a maternal arm is positioned to remain accessible in case unexpected invasive pressure monitoring is required (e.g., maternal hemodynamic instability). A large-bore venous catheter is placed for treatment of unexpected significant hemorrhage. Intravenous fluids administered to the mother are minimized (<2 L) to decrease the risk for perioperative pulmonary edema associated with the use of tocolytics, such as magnesium sulfate or administration of large doses of nitroglycerine during fetal surgery.[307] Some fetal surgery teams are more restrictive with intraoperative fluid administration (<500 mL), but no clinical trials have demonstrated benefit of severe intravenous fluid restriction in this setting.

Typical maternal hemodynamic goals include maintaining systolic arterial blood pressure within 10% of baseline values and mean arterial pressure greater than 65 mm Hg with appropriate maternal heart rate. Phenylephrine administration can be used to treat maternal hypotension with minimal changes in the fetal acid-base status.[308] Bolus administration of ephedrine or glycopyrrolate can assist in maintaining maternal heart rate and cardiac output.[309] Administration of a nondepolarizing muscle relaxant is usually unnecessary but may be used to improve operative conditions. If it is used, appropriate neuromuscular monitoring should be employed to carefully assess neuromuscular function with appropriate reversal of blockade before tracheal extubation, particularly with administration of magnesium sulfate, which potentiates neuromuscular blockade.

Before skin incision, the inspired concentration of volatile anesthetic is increased, and before uterine incision, the volatile anesthetic end-tidal concentration is further increased (≥ 2 MAC) to provide profound uterine relaxation. If uterine relaxation is assessed to be inadequate by appearance of contractions or palpation, administration of additional volatile agent (up to 3 MAC) or intravenous nitroglycerin as an infusion or in small boluses (50-200 μg) is useful to decrease uterine tone.[183]

An alternative technique, as mentioned earlier, relies on supplemental intravenous anesthesia. Administration of intravenous propofol and/or remifentanil with volatile anesthetic at 1.5 MAC may prevent fetal ventricular dysfunction as well as improve maternal hemodynamics, uterine blood flow, and fetal acid-base status, while reducing fetal exposure to high levels of volatile agents and providing adequate uterine relaxation.[283,286] A sheep model of this anesthetic regimen notes significantly lower fetal plasma concentrations of propofol compared to maternal concentrations.[288] Remifentanil pharmacokinetics in midgestation during fetal surgery have been shown to be similar to the general population,[310] and remifentanil is known to readily cross from maternal to fetal circulation.[287]

For rare patients with contraindications to volatile anesthetics (e.g., malignant hyperthermia), a neuraxial technique in conjunction with intravenous administration of nitroglycerin in doses up to 20 μg/kg/min has been used successfully for an EXIT procedure.[288] This technique may increase the risk for maternal pulmonary edema secondary to the large doses of nitroglycerin and therefore should be reserved for cases with a particular need. Currently, no specific anesthetic technique demonstrates significant improvement in fetal outcome.

Periodic ultrasonography is used to assess FHR and fetal cardiac function. In some open fetal procedures, pulse oximetry or additional direct fetal monitoring can be employed after the hysterotomy is performed, as previously discussed in the section on fetal physiology and monitoring. Rarely, when uncertainty exists regarding fetal condition, umbilical cord blood gas measurements can be obtained. As described in the prior section on fetal anesthesia, analgesia, and pain perception, an opioid and a muscle relaxant can be administered to the fetus intramuscularly either before uterine incision with ultrasound guidance or under direct vision after uterine incision. Intramuscular atropine also can be administered concurrently to reduce opioid-induced fetal bradycardia.

After uterine exposure and ultrasound placental mapping, a small hysterotomy is created away from the placenta. A stapling device with absorbable lactomer staples is used to extend the incision. The staples prevent hemorrhage from the relaxed uterus and seal the amniotic membranes to the uterine endometrium. Uterine blood loss can be rapid and difficult to estimate. Vigilant observation of the surgical field, close communication with the surgeon, and careful maternal monitoring are essential to avoid occult hemorrhage. Lost amniotic fluid is replaced with warmed crystalloid to bathe the exposed fetus. Intrauterine temperature is closely monitored to prevent hypothermia and associated fetal circulatory compromise.[253,254]

For fetal mass resections or other open procedures with high risk for significant fetal blood loss, an intravenous catheter should be placed in a fetal limb for blood and fluid administration by the anesthesiologist. All blood or fluids transfused to the fetus should be warmed. In urgent situations, fluids can be transfused directly into the umbilical vein through catheter access obtained in the operative field if a fetal peripheral intravenous line is not available.

In the rare event of maternal hemodynamic collapse, if maternal resuscitation has been unsuccessful in restoring adequate maternal hemodynamics after 4 minutes, the fetus should be delivered emergently to relieve aortocaval compression, improve maternal resuscitation efforts, and increase the chance for maternal survival.[311] A neonatologist and neonatal resuscitation team should be readily available in case of emergency delivery. Newborn resuscitation should proceed according to the current recommended guidelines.[312]

After completion of the fetal procedure, an initial loading dose of intravenous magnesium sulfate (4-6 g) is typically administered over 20 minutes during uterine closure to prevent uterine contractions.[313] After the bolus, an intravenous infusion of magnesium sulfate (1-2 g/h) is initiated to maintain uterine quiescence into the postoperative period. The inspired concentration of volatile anesthetic is significantly decreased or discontinued after the magnesium sulfate bolus is complete. After an epidural test dose, epidural anesthesia is initiated. Maternal anesthesia is maintained with epidural anesthesia and supplemented by administration of intravenous opioid, inhaled anesthetics, and/or intravenous propofol. The mother's trachea is extubated after she awakens and after confirming adequate neuromuscular recovery and hemodynamic stability.

Postoperative Management and Considerations

In addition to postoperative concerns associated with a cesarean delivery (i.e., pain management, prevention of venous thromboembolism, monitoring for hemorrhage, avoiding wound infection), postoperative care of patients undergoing fetal surgery also focuses on tocolysis and fetal monitoring. For minimally invasive procedures such as cordocentesis or IUT, tocolysis is typically not required. For more invasive percutaneous procedures (e.g., shunt placement, fetoscopic techniques), preoperative prophylactic tocolytic agents such as indomethacin may be administered. Additional tocolytic drugs are rarely required in the postoperative period.

After open fetal surgery, patients frequently experience early uterine contractions and require continuous uterine monitoring for 2 or 3 days. Management of postoperative preterm labor after fetal surgery is a challenge and has led to significant fetal morbidity from preterm delivery. Magnesium sulfate infusions initiated intraoperatively are continued for approximately 24 hours or more postoperatively. Additional tocolytic agents (e.g., indomethacin, terbutaline, nifedipine) are often necessary. Administration of indomethacin requires periodic fetal echocardiography monitoring because premature closure of the ductus arteriosus is a known complication of therapy. In Europe, atosiban, an oxytocin receptor antagonist, has been shown to provide efficacious tocolysis following open fetal MMC repair with less maternal side effects.[314] Atosiban is currently not available for use in the United States.

The fetus is evaluated postoperatively by ultrasonography. Continuous FHR monitoring is used in the postoperative period. The duration of monitoring is based on GA and fetal condition. Potential fetal morbidities includes infection, heart failure, intracranial hemorrhage, oligohydramnios, and fetal demise. If maternal pulmonary edema is suspected, a chest radiograph should be obtained and critical care admission may be required.

For minimally invasive procedures, satisfactory postoperative analgesia is typically achieved by administration of oral opioid-based pain medications and acetaminophen. For open procedures, postoperative epidural analgesia can initially be provided for a day or two using a dilute solution of local anesthetic and opioid. Intravenous opioids administered with a patient-controlled device can be used in place of an epidural or after the epidural is discontinued. Use of opioids can decrease FHR variability[315] and create some difficulty in FHR tracing interpretation. Inadequate postoperative pain control can increase plasma oxytocin levels and increase the risk for preterm labor.[316]

After open fetal procedures, patients are at high risk for PROM, preterm labor, infection, and uterine rupture.[4] In addition to these risks, periodic assessment of fetal well-being, growth, and integrity of the pregnancy necessitate the mother remain near the fetal treatment institution for the first few weeks after the procedure. The possibility of preterm delivery may necessitate a course of steroids to improve fetal lung maturity. After open procedures, cesarean delivery is often planned for 37 weeks gestation but may be required earlier with the onset of preterm labor. The recent hysterotomy increases the chance for uterine rupture and associated need for emergent cesarean delivery.[317]

Management of Ex Utero Intrapartum Treatment Procedure

Although the initial purpose of the EXIT procedure was to provide a controlled and stable means to remove the tracheal occlusive device previously placed in the fetal airway for in utero treatment of CDH, the EXIT procedure has expanded into a technique used for a variety of other fetal disorders (Table 63.7).[10,12,275,286,318] The EXIT procedure allows the fetus to remain supported by the placental unit with adequate oxygenation and perfusion while airway, surgical repair, and resuscitation interventions are performed in a controlled manner. The procedure has been used successfully to treat fetuses requiring intrathoracic mass resection, as a bridge to ECMO, and in separation of conjoined twins.

TABLE 63.7 Indications for the Ex Utero Intrapartum Therapy Procedure

Procedure	Reason	Fetal Malformation
EXIT-to-Airway	Intrinsic compression	Congenital high airway obstruction syndrome Laryngeal atresia/stenosis Tracheal atresia/stenosis Laryngeal web/cyst
	Extrinsic compression	Cervical teratoma Cystic hygroma Epulis Goiter Hemangioma Lymphangioma Neuroblastoma
	Iatrogenic	Removal of tracheal occlusive device placed to treat CDH
	Craniofacial	Severe micrognathia Severe retrognathia
EXIT-to-Resection	Intrathoracic airway compromise or Mediastinal compression	Bronchogenic cysts Bronchopulmonary sequestration Congenital pulmonary airway malformation Mediastinal mass Thoracic tumor
EXIT-to-ECMO	Cardiopulmonary compromise	Aortic stenosis with intact/restrictive atrial septum CDH with severe pulmonary compromise Hypoplastic left heart syndrome with intact/restrictive atrial septum
EXIT-to-Separation	Prolonged surgical compromise	Conjoined twins

CDH, Congenital diaphragmatic hernia.

Modified from Hoagland MA, Chatterjee D. Anesthesia for fetal surgery. *Paediatr Aneasth*. 2017;27:346–357.

The primary goals of the EXIT procedure are to maintain a prolonged state of uterine relaxation, delay placental separation, and sustain placental-fetal perfusion. Similar to open fetal surgery, EXIT procedures are frequently performed under general anesthesia, employing high concentrations (≥2 MAC) of volatile anesthetic to ensure uterine relaxation. Neuraxial anesthesia in combination with remifentanil and nitroglycerin has been used successfully.[288,319-321] Multiple reviews of the anesthesia, surgical, and obstetric considerations for the EXIT procedure have been published.[10,11,275,286,322] The overall preoperative and intraoperative approach for anesthetic management is similar to that previously described for the preoperative and intraoperative portions of open fetal surgery (see Box 63.2).

The primary difference occurs after delivery of the fetus, when uterine relaxation is no longer required. Thus, after delivery of the neonate, anesthetic management becomes similar to management of a cesarean delivery under general anesthesia.

A detailed multidisciplinary meeting is extremely valuable before the start of the EXIT procedure. It is essential to ensure that all required supplies for fetal monitoring; airway management; maternal, fetal, and newborn resuscitation; and postdelivery care are obtained before entering the operating room. In many situations, the case may present urgently, and having a predetermined checklist and cart with needed EXIT supplies can be extremely useful. In addition to fetal ultrasonography, a pulse oximeter is frequently used to monitor the fetus and can assist with confirmation of a secured airway in addition to capnography. Similar to open fetal surgery, weight-based doses of atropine, epinephrine, and calcium are prepared for possible emergency fetal resuscitation. A sterile fetal ventilation circuit with an air/O_2 source and manometer is prepared in addition to multiple sizes of endotracheal tubes, and laryngoscopes, and blades for fetal tracheal intubation. Both rigid and flexible neonatal bronchoscopes are also useful. Sterile tourniquets, intravenous catheters, crystalloid, and blood (i.e., O-negative, CMV-negative, leukocyte depleted, maternally crossmatched) should be available for fetal venous access and volume replacement.

Anesthetic considerations for the mother are similar to those for open fetal surgery (see Box 63.2). They include possible placement of a preoperative epidural catheter for postoperative analgesia, large-bore intravenous access, invasive monitoring readily available or placement of an intraarterial catheter, uterotonic drugs after delivery of the placenta, and crossmatched maternal blood in the operating room. Anesthetic induction and tracheal intubation are similar to general anesthetic techniques employed for cesarean delivery. Maintenance of appropriate maternal hemodynamics is critical to ensure adequate fetal perfusion. Similar to techniques used for open fetal surgery, high concentrations of a volatile anesthetic (≥2 MAC) with or without intravenous administration of nitroglycerin bolus doses (100-250 μg) or as an infusion (1-10 μg/kg/min) may be required for adequate uterine relaxation. Fetal anesthesia from transplacental transfer of maternal volatile anesthetic can be supplemented with fetal intramuscular administration of an opioid (e.g., fentanyl 5-15 μg/kg or morphine 0.1 mg/kg) and a paralytic agent (rocuronium 2.5 mg/kg or vecuronium 0.3 mg/kg). Sometimes intramuscular atropine (20 μg/kg) is administered to prevent fetal bradycardia. The intramuscular fetal anesthetic drugs can be administered either before uterine incision using ultrasound guidance or under direct vision after performing the hysterotomy. There is significant variation in fetal serum fentanyl concentrations based on umbilical cord blood sampling during EXIT procedures.[323] It is likely that significant variability also may exist with fetal serum concentrations of muscle relaxants and other agents administered to the fetus, making their pharmacologic actions less predictable.

An alternative anesthetic approach uses maternal neuraxial anesthesia combined with intravenous administration of nitroglycerin in an effort to avoid many of the risks associated with administration of general anesthesia as previously described.[288,319-321] Significant doses of intravenous nitroglycerin (1-10 μg/kg/min) are often required to achieve uterine relaxation. Although nitroglycerin crosses the placenta, there are minimal fetal effects because a significant amount is metabolized at the placental interface.[288,320] Invasive monitoring with a maternal intraarterial catheter is recommended when prolonged use of nitroglycerin is planned, and the patient should be monitored for onset of pulmonary edema. Some practitioners have also added a remifentanil infusion (0.1-0.3 mcg/kg/min) to the anesthetic regimen. Intravenous remifentanil administered to the mother rapidly crosses the placenta,[287] and has been reported to provide adequate fetal immobilization.[319,321] No prospective clinical trials have been conducted to determine the best anesthetic technique for the EXIT procedure.

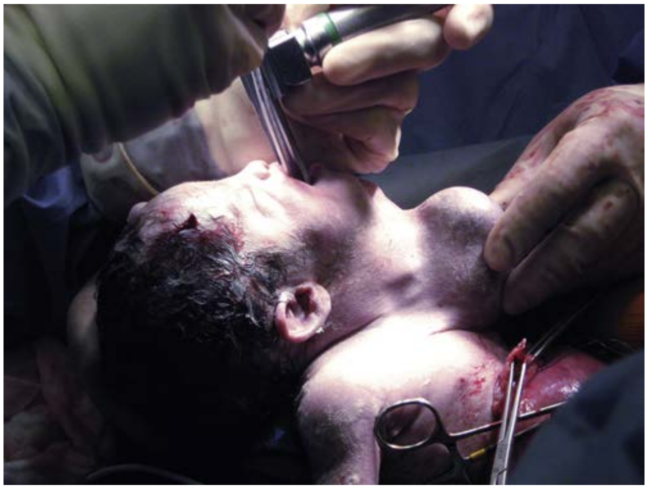

Fig. 63.13 During an ex utero intrapartum therapy procedure, the head and upper torso of a fetus with a neck mass are delivered and the airway secured using direct laryngoscopy. (Courtesy Dr. Anita Moon-Grady, University of California, San Francisco Fetal Treatment Center, San Francisco, CA.)

After assessment of appropriate uterine relaxation, the placental border is determined by ultrasonography. A small initial hysterotomy is extended outside the placental border with a stapling device to prevent excessive blood loss. If the EXIT procedure is performed to facilitate fetal intubation or neck mass resection, only the fetal head and shoulders are initially delivered (Fig. 63.13). For more extensive procedures requiring access to the thorax or other anatomic locations, the entire body may be delivered.

Before hysterotomy, the fetus is monitored with echocardiography and ultrasonographic evaluation of umbilical cord flow. After hysterotomy, a pulse oximeter probe is placed on the fetal hand and shielded from ambient light. Warmed crystalloid fluids are irrigated continuously in the uterine cavity to maintain fetal temperature and prevent placental separation or spasm of umbilical vessels. Care should also be taken to avoid inadvertent compression or unnecessary manipulation of the umbilical cord, which could lead to vascular reactivity and decreased flow.

Depending on the indication, the duration of an EXIT procedure ranges from a few minutes (e.g., intubation) to several hours (intrathoracic mass resection, neck mass resection with tracheostomy, or ECMO cannulation).

Anesthetic techniques have successfully provided safe maternal and fetal anesthesia with uterine relaxation and uteroplacental stability over several hours.[324] Before ventilation of the fetal lungs, fetal oxyhemoglobin saturation is typically 40% to 70%.[325] After initiating ventilation of the fetal lungs, oxyhemoglobin saturation should increase significantly to above 90%. When fetal lung ventilation fails to result in an appropriate increase in oxyhemoglobin saturation despite appropriate endotracheal intubation, this represents an indication for ECMO initiation before clamping the umbilical cord and fetal delivery.[326] Capnography is beneficial in confirming correct placement of the endotracheal tube. If needed, pulmonary surfactant may be administered once the endotracheal tube is placed. Transporting the neonate to the intensive care area for further care requires significant vigilance to ensure the critical, tentative airway remains secured.

Once the fetus is delivered, the inspired concentration of the volatile agent is significantly decreased and the nitroglycerin infusion is stopped to allow the uterus to contract and diminish the risk for maternal hemorrhage.[327,328] Use of a combination of volatile anesthetics (≤0.5 MAC), nitrous oxide, propofol, and/or an opioid can maintain adequate anesthesia while allowing uterine tone to improve. Oxytocin is routinely administered and additional uterotonic drugs are also provided when necessary, as detailed in Chapter 62. Once the patient is hemodynamically stable with appropriate uterine tone, epidural analgesia may be initiated. The trachea is extubated once the mother is fully awake.

Conclusions and Future Considerations

Establishment of organized, multidisciplinary, and comprehensive fetal intervention programs at a variety of academic centers is critical to improving patient outcomes with innovative surgical techniques, refining diagnostic and treatment strategies, and initiating clinical trials powered to address long-term neonatal outcomes and associated maternal and neonatal morbidity. Advancement of surgical techniques and prenatal diagnostic and management strategies is likely to decrease both maternal and fetal risk and allow safe intervention for additional congenital anomalies and treatment of less severe abnormalities. In addition, in utero stem cell and gene therapy research may lead to novel fetal treatments that allow normal development despite the presence of a congenital anomaly.[329-331] Improvements in managing preterm labor and delivery would greatly improve outcomes in fetal therapy. Preterm birth is associated with morbidities such as respiratory distress syndrome, necrotizing enterocolitis, and intraventricular hemorrhage that all have long-term impact on the child and carry substantial cost.[332] Artificial placental units employing extracorporeal support of the preterm neonate with continuous fluid exchange are novel therapies currently being tested in animals.[333]

Fetal surgery is a relatively new and rapidly evolving area of clinical medicine. In utero treatment raises complex and difficult ethical, social, and legal issues that go far beyond that of most adult or pediatric surgical interventions and include questions regarding maternal rights, access to care, and the option for pregnancy termination.[334,335] Evaluation of each new therapy or change in treatment strategy should be conducted in multicenter clinical trials only after appropriate translational research and animal studies are completed and demonstrate a potential benefit. This transition from innovative breakthrough, to randomized clinical trial, to standard care must be managed in a responsible and ethical framework.

In addition, in utero treatment outcomes from new institutions with minimal experience and intervention for patients outside the strict inclusion criteria of clinical trials are likely to result in less favorable results with increased morbidity compared with the outcomes demonstrated at more established fetal treatment centers participating in the clinical trials.[336] To address these concerns, a bioethics committee from the American College of Obstetricians and Gynecologists and the American Academy of Pediatrics provided recommendations for centers offering fetal therapy.[6] Their recommendations included a thorough informed consent process, appropriate institutional research safeguards, involvement of a multidisciplinary team, and the need for open collaborative research networks. Although this approach has high financial costs, thorough basic science and translational and clinical research in fetal therapy is essential to appropriately manage the unique risks and benefits of future innovations. Appropriate patient selection (both maternal and fetal) and timing of the intervention also need to be better established in many of the procedures.

The principal of *primum non nocere* argues that until a therapy is appropriately tested in animal models, it is unethical to pursue in human trials.[337] Advances in fetal surgery not only require determination of fetal benefit but also must be powered to appropriately evaluate additional fetal and maternal morbidity.[338] Only the results of animal research and descriptive summaries of clinical series currently guide the majority of clinical anesthetic care for fetal surgery. Further rigorous research is needed to determine optimal anesthetic techniques, ensure maternal and fetal cardiovascular stability, improve our understanding of anesthetic exposure and neurocognitive deficits, assess the impact of anesthetic management strategies on uterine tone and uteroplacental perfusion, and to improve our ability to determine the adequacy of fetal anesthesia to produce immobility and block the fetal stress response.[276,339]

Areas of clinical growth include programs for anesthesia training in fetal treatment and the development of standard guidelines for fetal anesthesia and perioperative care of these unique procedures. Fetal treatment is a relatively new, rapidly evolving field of clinical medicine that holds great promise for treating morbid conditions and improving quality of life over the entire lifetime of the patient. Equally significant are the research efforts, technologic advancements, and ethical standards that must be supported to achieve these goals.

Anesthesia for Orthopedic Surgery

CHRISTOPH H. KINDLER, OLEG V. EVGENOV, LANE C. CRAWFORD,
RAFAEL VAZQUEZ, JASON M. LEWIS, and ALA NOZARI

KEY POINTS

- Degenerative joint disease is the foremost medical condition leading to operations in the United States. With continued population growth and an increasing percentage of older people, a fivefold increase in the demand for hip and knee arthroplasty and spine procedures is projected by 2030.
- Many orthopedic operations including total joint arthroplasties and spine surgeries are classified as intermediate surgical risk, with 30-day cardiac death or myocardial infarction occurring with an incidence of 1% to 5%. Since preoperative cardiac risk evaluation is often inconclusive in high-risk patients with limited mobility, a higher level of monitoring and perioperative troponin measurements should be considered to assess for perioperative cardiac events.
- Comprehensive preoperative geriatric assessment is increasingly used in the perioperative care of older patients who may have multiple comorbid conditions and who have suffered fragility fractures. Prehabilitation programs can be useful in these patients to reduce frailty and improve surgical outcome.
- Fractures of the proximal femur following falls are common in older patients and are associated with high morbidity and mortality. Early surgery (<24 hours) has been associated with reduced pain and length of hospital stay. Patients with significant medical comorbidities that delay surgery for more than 4 days have a higher mortality.
- As compared to the lateral position, beach chair position offers superior surgical exposure and access for most shoulder surgeries, less distortion of muscle anatomy, and less tension on the brachial plexus. Cerebral perfusion pressure can decrease by 15% in sitting patients under general anesthesia, and in patients with cerebrovascular disease detrimental decrease in cerebral blood flow can occur if the systemic pressure is not carefully monitored and maintained. The role of the sitting position on postoperative neurologic outcome remains, however, controversial.
- The most common complications after total hip arthroplasty and total knee arthroplasty are cardiac events, pulmonary embolism, pneumonia and respiratory failure, and infections. Older patients with major comorbidities including cardiac disease, pulmonary disease, and diabetes should have a complete preoperative medical evaluation.
- Cemented fixation of the femoral prosthesis can be complicated by the bone-cement implantation syndrome, resulting in intraoperative hypotension, hypoxia, or even cardiac arrest. Invasive hemodynamic monitoring with an arterial catheter and possibly also a central venous catheter should be considered. Treatment with a potent inotropic agent such as epinephrine may be required. Pulsatile lavage of the femoral canal and drilling a vent hole in the femur before prosthesis insertion can also ameliorate the hemodynamic consequences of this devastating complication.
- Correction of spinal deformities can be associated with large intraoperative blood loss, and measures to minimize blood transfusion should be considered. Deliberate controlled hypotension has been employed but must be used with caution in older adults, those with cardiovascular disease, or those at risk for ischemic complications and postoperative vision loss. Antifibrinolytic agents may be considered to limit blood loss but should be avoided in patients with a history of thromboembolic events, coronary stents, or renal impairment.
- Intraoperative neurophysiologic monitoring is increasingly employed for spine surgeries and is currently recommended for procedures with increased risk for spinal cord injury including correction of spine deformities, resection of intramural tumors, unstable spine trauma, Chiari malformation, spinal cord vascular malformations, as well as those with risk for root damage and in patients with significant risk for compression neuropathies.
- Perioperative visual loss after spine surgery can be caused by anterior or posterior ischemic optic neuropathy, retinal ischemia, cortical blindness, or posterior reversible encephalopathy. Direct pressure on the eye should be avoided and patients should be positioned so that the head is level with or higher than the heart. The patient's head should be maintained in a neutral forward position without significant neck flexion, extension, lateral flexion, or rotation. Staged spine surgery procedures can reduce the risk of perioperative visual loss and should be considered in high-risk patients.

Preoperative Evaluation

EPIDEMIOLOGY AND DEMOGRAPHICS OF ORTHOPEDIC SURGERY

Orthopedic operations represent the most frequently performed procedures in U.S. hospitals. Arthroplasty of the knee was the single operation performed most often during U.S. hospital stays in the year 2012, amounting to 700,100 operating room procedures (223 per 100,000 population). Hip replacement surgery with 468,000 operations (149 per 100,000 population) was the fourth most frequent operation and spinal fusion, with 450,900 operations (144 per 100,000 population), the fifth.[1]

These statistics highlight the magnitude of degenerative joint disease, or osteoarthritis (OA), as the foremost medical condition leading to operations in U.S. hospitals. OA is the most common form of arthritis, affecting over 54 million U.S. adults according to 2018 data (78 million U.S. adults are expected to be affected in the year 2045).[2] The lifetime risk of developing OA of the knee is about 46%, and that of the hip is 25% according to the Johnston County Osteoarthritis Project.[3,4]

With age as a prominent risk factor for developing osteoarthritis and with an increasing percentage of elderly people in general, termed population aging (we are expecting 83.7 million US citizens older than 65 years in 2050, almost double the 2012 estimate of 43.1 million for that age group) (Fig. 64.1A and B),[5] the demand for primary total knee arthroplasty is projected to increase by the year 2030 by approximately 5-fold, amounting to 3.4 million surgeries expected to be performed annually in the US (Fig. 64.2A and B).[6,7]

Given the increasing number of patients and volume-based need for orthopedic surgery, every anesthesiologist will sooner

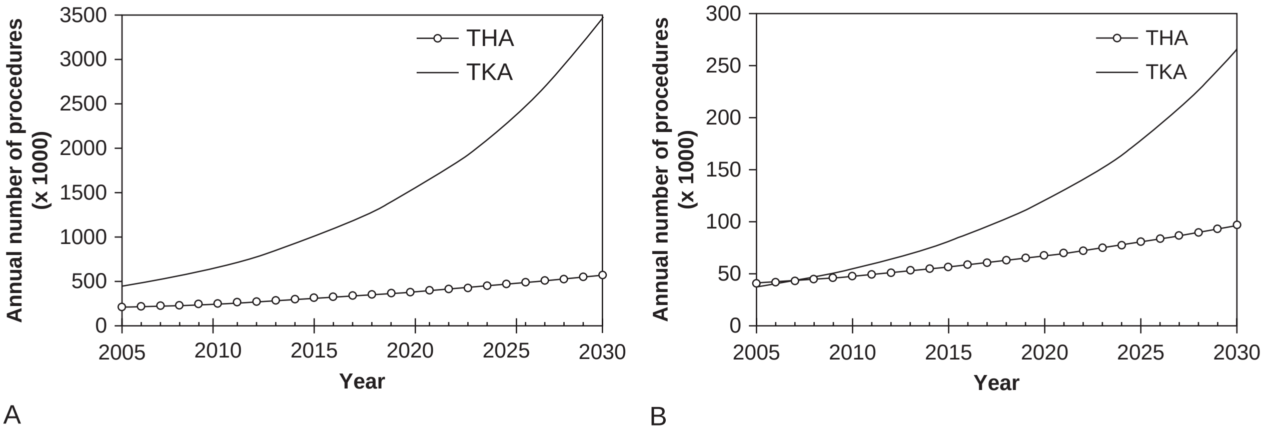

Fig. 64.2 The projected numbers of primary (A) and revision (B) total hip arthroplasties *(THA)* and total knee arthroplasties *(TKA)* in the United States **from 2005 to 2030.** (With permission from Kurtz S, Ong K, Lau E, et al. Projections of primary and revision hip and knee arthroplasty in the United States from 2005 to 2030. *J Bone Joint Surg Am*. 2007;89(4):780–785.)

or later become an orthopedic anesthesiologist. Population aging with the corresponding low support ratio (defined by the number of workers divided by retirees) will also inevitably cause political and financial pressures on public healthcare systems.[8] In particular, financial pressures will certainly intensify and be passed on to orthopedic surgery and anesthesia with its age-related increase in frequency and volume.

It is not surprising that in 2013 the OA-attributable medical costs in the United States were estimated to be $140 billion, with the total medical expenditures and earning losses as high as $304 billion.[9] When conservative therapy including physical activity with muscle strengthening, flexibility and balance exercises, weight control, pain medications, and other personal coping strategies fail to control the symptoms of OA, joint replacement surgery is often the last option for patients suffering from OA to relieve pain and regain mobility.

Using the traditional accounting method, the total cost per hip replacement was recently estimated to be 22,000 to 27,000 USD,[10,11] and for the total cost per knee replacement, 29,500 USD.[11] It is, therefore, not surprising that OA is among the most expensive medical conditions to treat when joint replacement surgery is required. In fact, OA was, following septicemia, the second most expensive health condition treated at U.S. hospitals in 2013. In that year, OA accounted for $16.5 billion, or 4.3% of the combined costs of all U.S. hospitalizations. OA was also the most expensive condition for which privately insured patients were hospitalized, accounting for over $6.2 billion in hospital costs and amounting to 3.6% of the combined costs for all private hospitalizations.[12]

In the past, there was a natural reluctance to perform total joint arthroplasties on very old patients. Older studies reported not only limited evidence of favorable pain and functional outcome of these procedures in patients aged 80 years or older, but also higher rates of complications and mortality.[13-18] Some of these studies were undersized, only used a descriptive or retrospective design, and were also challenged by case-control or prospective community-based studies that failed to report higher complication rates in older age groups.[19-21] The main conclusion of these authors was that with increased life expectancy and elective surgery improving the quality of life, age alone is no longer a factor that affects the outcome of total joint arthroplasty and should, therefore, not be a limitation when deciding who should receive this surgery. Over the past 20 years, arthroplasties in octogenarians and even nonagenarians have become routine procedures in many orthopedic institutions. Nevertheless, a recent study including 7569 patients reported a greater risk of perioperative mortality (relative risk [RR] 3.69; confidence interval [CI], 1.37-9.93), pneumonia, and urinary tract infection in patients 80 years of age or older undergoing aseptic revision total hip arthroplasty (THA).[22] This same study also found general anesthesia compared with epidural, spinal, regional, or monitored anesthesia care to be an independent risk factor for serious adverse events in these patients (RR 1.90; 95% CI, 1.29-2.79).

Considering this enormous financial expenditure combined with the increased age and accompanying comorbidities of the orthopedic patients, anesthesiologists must be highly skilled and apply their utmost vigilance when planning the anesthetic course, including counseling the patient, identifying at-risk patients, and selecting appropriate perioperative anesthetic management and postoperative care.

CARDIOVASCULAR COMORBIDITIES

Coronary Artery Disease

With regard to cardiac risk, surgical interventions can be broadly divided into low-risk, intermediate-risk, and high-risk groups with estimated 30-day cardiac events (cardiac death and myocardial infarction) of less than 1%, 1% to 5%, and more than 5%, respectively.[23] The vast majority of orthopedic operations, such as total joint arthroplasties and spine surgery, are considered and classified as an intermediate surgical risk with 30-day cardiac death or myocardial infarction occurring in 1% to 5% of patients. In fact, most studies have reported a primarily perioperative, acute myocardial infarction rate after hip or knee arthroplasty of 0.3% to 1.8%.[24-26] A recent study defining the intrinsic cardiac risk of a single specified operation rather than groups of operations to improve upon current preoperative cardiac-risk assessment strategies also considered THA as an intermediate intrinsic cardiac risk with an odds ratio (OR) of 0.95 (95% CI, 0.83-1.08) relative to the statistically estimated average procedure.[27] Another interesting study, using

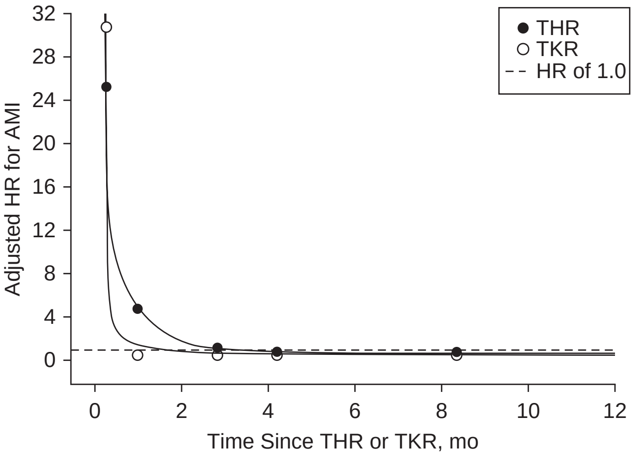

Fig. 64.3 Adjusted hazard ratios *(HR)* for acute myocardial infarction *(AMI)* in patients undergoing total hip replacement *(THR)* and total knee replacement *(TKR)* with respect to time since the operation (mo = months). (With permission from Lalmohamed A, Vestergaard P, Klop C, et al. Timing of acute myocardial infarction in patients undergoing total hip or knee replacement: a nationwide cohort study. *Arch Intern Med.* 2012;172(16):1229–1235.)

matched controls not undergoing surgery, demonstrated an increased risk of acute myocardial infarction during the first 2 weeks after total hip replacement (25-fold) and after total knee replacement (31-fold). The association of an increased cardiac risk and surgery was strongest in patients 80 years of age or older. Interestingly, the risk of acute myocardial infarction decreases significantly after 2 weeks, although it remains elevated during the first 6 weeks for total hip replacement patients (Fig. 64.3).[28]

Over the last 40 years, several indices and scores were developed to better determine perioperative cardiac risk.[29] The first was introduced in 1977 by Lee Goldman.[30] The most widely used of these risk indices today remains the Revised Cardiac Risk Index (RCRI).[31] More recently, a new perioperative risk index known as the Gupta score was proposed using a new model and an up-to-date and simplified approach, which is also available as a risk calculator on the Internet.[32] It was validated on a cohort of more than 400,000 patients of the National Surgical Quality Improvement Program database and uses the American Society of Anesthesiologists (ASA) classification system, dependent functional status, age, abnormal creatinine, and type of surgery as main factors associated with cardiac risk after surgery. In this study, the adjusted OR for myocardial infarction or cardiac arrest was estimated to be 2.22 (95% CI, 1.55-3.17) for orthopedic surgery and 1.24 (95% CI, 0.38-4.00) for spine surgery, compared with an OR of 4.96 for aortic surgery. With a growing geriatric population and an increase in elective noncardiac surgeries in these patients, the necessity of having accurate estimations of the cardiac risk for geriatric patients becomes obvious. For this reason, the new geriatric-sensitive perioperative cardiac risk index (GSCRI), derived solely from geriatric data, was developed in 2017.[33] The GSCRI model contains a total of seven variables, where the main three statistically important variables associated with cardiac risk in the older adult were stroke history, ASA class, and surgical category. Compared to the Gupta score, the GSCRI model considers heart failure, stroke history, and diabetes mellitus status as additional variables. The GSCRI has been shown to be a significantly better predictor of cardiac risk in geriatric patients undergoing noncardiac surgery compared to the Gupta score and RCRI. In the GSCRI, the OR for myocardial infarction or cardiac arrest in orthopedic patients (OR, 2.99; 95% CI, 2.22-4.02) was higher than in the other two indices. The underestimated cardiac risk in geriatric patients resulting from these scores is likely due to estimates that were derived from a younger population.[33]

During the last few years, the focus of cardiac risk has somewhat changed, and perioperative myocardial injury (PMI) has gained increased importance as an additional risk factor for postoperative cardiac events.[34,35] High-sensitivity cardiac troponin assays have been introduced as an important biomarker in routine clinical care. Such novel biomarkers can detect patients at risk beyond established risk scores, and the measurement of these troponins allows for detection of acute cardiomyocyte injury during the perioperative period.[35] PMI is mainly defined by a perioperative increase of absolute or relative troponin values using delta or maximum postoperative values. Despite the current lack of a clear and uniform international definition for PMI, this entity has recently been identified as an important, yet often undetected, complication of noncardiac surgery that is strongly associated with 30-day mortality.[34,36,37] In the most recent study on PMI, Puelacher and coauthors defined PMI as an absolute increase in high-sensitivity cardiac troponin of 14 ng/L or greater from preoperative to postoperative measurements in high-risk patients 65 years or older or in patients 45 years or older with a history of preexisting coronary artery disease, peripheral artery disease, or stroke.[38] In their study population of over 2000 patients, they found an incidence of PMI in orthopedic patients undergoing an intermediate-risk surgical procedure (e.g., total hip or knee replacement) of 20% and for spinal surgery an incidence of PMI of 15% (Table 64.1). With PMI being associated with an overall substantial 30-day mortality as high as 9% and 1-year mortality as high as 22%, recommendations have already been published for screening high-risk patients for PMI.[39] The Canadian Cardiovascular Society Guidelines on perioperative cardiac risk assessment and management of patients undergoing noncardiac surgery already explicitly recommend obtaining daily troponin measurements for 48 to 72 hours after noncardiac surgery in high-risk patients.[40] These perioperative troponin measurements may be particularly useful in high-risk orthopedic patients, since the preoperative cardiac risk evaluation is often inconclusive due to the limited mobility in these patients.

Other Cardiac Comorbidities

Coronary artery disease is probably the single most important cardiac risk factor in orthopedic patients. However, other cardiac diseases such as valvular heart disease or pulmonary hypertension are also important to detect and assess during the preoperative evaluation. Pulmonary hypertension is particularly important in orthopedic patients. In light of the effect of a potentially increased intrathoracic pressure on right heart diastolic function during certain procedures and positioning, the increased risk of venous thromboembolism and the risk of pulmonary embolism of intramedullary contents including fat, bone debris, and cement possibly exacerbating and worsening preexisting right heart strain need to be considered.

TABLE 64.1 Incidence of Perioperative Myocardial Injury in Patients with Increased Cardiovascular Risk (Patients Aged ≥65 Years or Patients with Preexisting Coronary Artery Disease, Peripheral Artery Disease, or Stroke)

		ESC/ESA SURGICAL RISK		
	Incidence of PMI [95% CI]	**<1%**	**1-5%**	**>5%**
All surgical specialties	16% [14-17] (397/2546)	9% [9-13] (79/833)	17% [19-23] (248/1432)	25% [28-39] (70/281)
Orthopedic	16% [12-20] (50/315)	10% [6-18] (12/115)	20% [15-26] (36/183)	12% [2-36] (2/17)
Trauma	18% [15-22] (83/455)	12% [8-17] (22/188)	23% [19-29] (61/260)	0% [0-41] (0/7)
Spinal	15% [11-19] (55/372)	19% [6-44] (3/16)	15% [11-19] (52/356)	0% [0] (0/0)

CI, confidence interval; *ESA*, European Society of Anaesthesiology; *ESC*, European Society of Cardiology; *PMI*, perioperative myocardial injury.
From Puelacher C, Lurati Buse G, Seeberger D, et al. Perioperative myocardial injury after non-cardiac surgery. *Circulation.* 2018;137:1221–1232.

Pulmonary hypertension is hemodynamically defined as a resting mean pulmonary arterial pressure of 25 mm Hg or greater and is classified into five groups: (1) patients with primary pulmonary arterial hypertension, (2) patients with pulmonary hypertension due to left heart disease, (3) patients with pulmonary hypertension due to chronic lung disease and/or hypoxia, (4) patients with chronic thromboembolic pulmonary hypertension, and (5) patients with unclear, mixed, or multifactorial reasons for pulmonary hypertension.[41] A number of retrospective studies reported the considerable risk of morbidity and mortality in patients with pulmonary hypertension undergoing noncardiac surgery with mortality ranging from 3.5% to 18%.[42,43] Major or emergency surgery, long procedure (more than 3 hours), high ASA class score, concomitant cardiovascular disease, poor exercise tolerance, higher preoperative pulmonary artery pressure, and the diagnosis of primary arterial hypertension have all been associated with adverse outcomes in these patients.[43,44] Ramakrishna and associates retrospectively identified 146 patients with pulmonary hypertension undergoing various noncardiac surgical interventions and reported a mortality rate of 7%. When the authors stratified risk by type of surgery, they found that 17% of patients undergoing low-risk surgical procedures experienced morbidity compared with 48% of those undergoing orthopedic surgery. This suggests that patients with pulmonary hypertension undergoing orthopedic surgery represent an especially vulnerable group.[45] Other authors examined 1359 patients with pulmonary hypertension undergoing THA and 2184 patients with pulmonary hypertension undergoing TKA. In-hospital mortality rates among patients with pulmonary hypertension increased by a factor of 3.72 (95% CI, 2.13-6.39) for the cohort undergoing hip arthroplasty compared with controls and by a factor of 4.55 (95% CI, 2.16-9.39) in patients undergoing TKA.[44] The highest rate of in-hospital mortality with 5% was reported in patients with primary pulmonary hypertension undergoing hip arthroplasty.

A thorough clinical examination of a patient with pulmonary hypertension should focus on the nature of symptom progression, exercise tolerance, signs of right ventricle failure, heart rate, blood pressure, electrocardiogram (ECG), chest radiography and biomarkers (B-type natriuretic peptide and high-sensitivity cardiac troponins). Further investigations may include arterial blood gases, echocardiography with estimation of pulmonary artery pressure, computed tomography (CT), coronary angiography, or even advanced and invasive hemodynamic measurements of pulmonary artery pressures and cardiac output depending on the severity of the disease.[42] Mortality of these surgical procedures can be reduced with careful planning, ideally in tertiary nationally designated pulmonary hypertension centers with close preoperative, intraoperative, and postoperative hemodynamic monitoring to prevent a pulmonary hypertension crisis.

Finally, it is important to also consider the noncardiac risks in the orthopedic population. At the moment, there is a lack of data on how noncardiac risk factors such as preoperative mental status, level of dependency, anemia, extreme low or high body weight, pulmonary risk factors, and immune status interact with the cardiovascular risk factors described earlier and how they impact the outcome of orthopedic surgery. There is a need for more general risk scores that can predict the outcome and mortality from noncardiac causes.[23] Therefore, in geriatric orthopedic patients it might be beneficial to obtain a more comprehensive estimation of a patient's functional reserves during the preoperative evaluation. This would also include noncardiac risk factors, rather than focusing on single-organ function and biomarkers alone. Too many healthcare systems are still organized around single-system illnesses. Today, frailty is increasingly recognized as an age-associated, multidimensional syndrome and a unique domain of health status that can be a valid marker of decreased reserves and of resulting perioperative vulnerability and unfavorable postoperative outcome in older patients.[46,47]

FRAILTY

It has long been known that older patients are at increased risk for postoperative complications, possibly due to reduced physiologic reserves to withstand an operation. Linda Fried was the first to use a validated scoring system to define this vulnerability (or frailty) in a more standardized manner and found that such preoperative characterization of frailty using five domains (weight loss, decreased grip strength, exhaustion, low physical activity, and slowed walking speed) could predict surgical outcomes such as postoperative complications, length of hospital stay, and discharge to a skilled- or assisted-living facility. Her frailty score also augmented other risk-assessment models such as the ASA score, the RCRI, or the Eagle's cardiac risk index.[46] Since the first description of this frailty concept in surgical patients, many additional frailty scores and scales including a vast diversity of variables have been proposed in the literature.

In orthopedic surgery, the Clinical Frailty Scale,[48] the FRAIL scale,[48] the modified Frailty Index (mFI),[49] the Groningen Frailty Indicator (GFI) questionnaire,[50] and the Frailty Phenotype and Frailty Index have all been used.[51] Flexman and associates showed in 52,671 patients that approximately 4% of the spine surgery population is frail and that the mFI independently predicted major postoperative complications (unadjusted odds ratio 1.58), prolonged length of stay (unadjusted odds ratio 1.89), discharge to a higher level of care (unadjusted odds ratio 2.29), and 30-day mortality (unadjusted odds ratio 2.05 for every 0.1 increase in frailty score) in patients undergoing surgery for degenerative spine disease.[49] In another study to assess feasibility and validity of the GFI questionnaire in patients undergoing total hip or knee arthroplasties, the authors reported that 33% of patients with hip OA and 24% of patients with knee OA were frail.[50] All studies examining frailty in elderly orthopedic patients reported a significant association with adverse postoperative outcomes such as surgical complications, hospital length of stay, discharge to post-acute institutional care, and readmission rate within 30 days.[48,51]

It has to be pointed out that frailty scales should be accompanied by a thorough clinical examination and comprehensive geriatric assessment including examining the burden of comorbidity, polypharmacy, physical function, psychological status, nutrition, risk of postoperative delirium, and social support to add further insights into the actual risk and the patient's real expectations.[52-54] Well-crafted comprehensive geriatric assessments can be a more powerful predictor of perioperative risk than the ASA score.[55] A study in older patients with a mean age of 78 years examining the prediction of postoperative morbidity and mortality using a comprehensive geriatric assessment reported a significantly higher risk for postoperative death or post-discharge institutionalization for orthopedic surgery compared with abdominal, thoracic, or other surgeries.[52] As such, the value of a comprehensive geriatric assessment has been particularly recognized as a promising system of care for complex older patients who have suffered fragility fractures.[56]

While frailty is increasingly acknowledged as a marker of functional decline, it remains a potentially modifiable risk factor. As such, preoperative rehabilitation programs have been introduced into clinical practice with the idea to reduce frailty and thereby improve surgical outcome. However, today the results of such prehabilitation programs remain controversial.[57-59]

NEUROLOGIC COMORBIDITIES

Stroke is a feared and devastating complication in the perioperative period and is associated with a high rate of morbidity and mortality.[60,61] Large studies have identified a rate of 0.2% for perioperative stroke following total joint arthroplasty, the incidence doubling to 0.4% in patients aged 75 years or older.[60,62] Mortazavi and associates reported advanced age, a history of cerebrovascular, coronary artery, atherosclerotic or cardiac valvular disease, atrial fibrillation or other intraoperative arrhythmias, urgent surgery, and general anesthesia as independent risk factors for stroke in patients undergoing total joint arthroplasties.[60] Compared with matched control subjects not undergoing surgery, Lalmohamed and associates reported a 4.7-fold increased risk of ischemic stroke and a 4.4-fold increased risk for hemorrhagic stroke during the first 2 weeks after THA. The risk remained significantly elevated for at least 6 weeks for ischemic stroke and 12 weeks for hemorrhagic stroke.[63] Since previous strokes represent a significant risk factor, a thorough evaluation of patients with neurologic diseases undergoing surgery can reduce perioperative morbidity and mortality.[64]

Postoperative delirium is recognized as the most common surgical complication in older adults, occurring in 5% to 50% of older patients after surgery. It is associated with major postoperative complications, including postoperative cognitive dysfunction and even death.[65] The main risk factors for postoperative delirium are well established and include among others age of 65 years or older chronic cognitive decline or dementia, poor vision or hearing, severe illness, and the presence of infection. In order to successfully prevent, predict, and manage postoperative delirium, different delirium risk scores were developed of which two were validated in orthopedic surgical patients.[66] Kalisvaart and associates implemented and validated a medical risk factor model in 603 hip surgery patients aged 70 years or older containing four factors: cognitive function at admission, visual impairment, acute physiologic and chronic health status, and blood urea nitrogen (BUN) to creatinine ratio.[67] One point was assigned for each of the four risk factors present, resulting in three groups: a low-, an intermediate-, and a high-risk group with incidences of delirium of 3.8%, 11.1%, and 37.1%, respectively. Cognitive impairment and age were the most important risk factors for delirium in this population of hip surgery patients. Postoperative delirium was four times as frequent in acute hip fracture patients as in elective hip replacement patients. Another study in elective hip or knee arthroplasty patients suggested the use of the Delirium Elderly At-Risk (DEAR) assessment, which incorporates the following risk factors: age, visual or hearing impairment, dependence in more than one activity of daily living, a low mini-mental state score on admission or a previous episode of postoperative delirium, and benzodiazepine or alcohol abuse.[68] A score of two or more using this tool was associated with a greatly increased risk of delirium. Logistic regression models showed the strongest associations of substance abuse and cognitive impairment with the development of postoperative delirium. In a prospective matched controlled cohort study, Kat and colleagues showed that the risk of dementia or mild cognitive impairment at 30 months follow-up is almost doubled in hip surgery patients aged 70 years or older with postoperative delirium compared with at-risk patients without delirium.[69] In addition, a recent study reported poor performance on a preoperative cognitive screening test in older patients undergoing hip or knee arthroplasties as a predictor of postoperative complications such as the development of postoperative delirium, a longer hospital stay, and a lower likelihood to return home in good health upon hospital discharge.[70] Postoperative delirium is also common after spine surgery in older adults and is also associated with increased length of stay, increased costs, and decreased odds of discharge to home.[71] All these studies clearly show the importance of incorporating the assessment of risk of delirium in the preoperative evaluation of elderly orthopedic patients.

THROMBOEMBOLIC DISEASE

Thromboembolic complications remain one of the leading causes of morbidity and mortality after orthopedic surgery. Antithrombotic guidelines are continuously updated and published by the American College of Chest Physicians (ACCP).[72] A systematic review and meta-analysis including 7 million pooled total joint arthroplasty patients found that cardiovascular disease, previous history of venous thromboembolism, neurologic disease, and ASA score were significant and independent risk factors for venous thromboembolism after joint arthroplasties.[73] Two large studies published after the last update of the ACCP guidelines suggested aspirin to be an effective, safe, convenient, and inexpensive alternative to low-molecular weight heparin or to rivaroxaban for extended thromboprophylaxis after joint arthroplasties.[74,75] In an evolving field with many new anticoagulation drugs available, accurate risk stratification would be helpful for physicians as well as patients. While the widely-used Caprini score risk assessment model for thromboembolic disease in the general surgical population failed to provide clinically useful risk stratification information in total joint arthroplasty patients,[76] a more individualized risk model improved the efficacy of preventing venous thromboembolism in these patients.[77] In spine surgery, venous thromboembolism prophylaxis remains even more controversial. An algorithmic approach to this problem was recently published to establish a more specific venous thromboembolism prophylaxis risk/benefit score for spinal surgery.[78]

With the increased use of percutaneous coronary interventions and other vascular stents, and the widespread use of oral anticoagulant drugs for atrial fibrillation or peripheral vascular disease, anesthesiologists are commonly involved in the perioperative management of patients with antiplatelet or anticoagulation therapy.[79] Moreover, a growing number of antiplatelet and anticoagulation therapies, including the non-vitamin K oral anticoagulants (novel or direct oral anticoagulants),[80-82] with unique pharmacodynamic and pharmacokinetic properties complicates the perioperative management of these patients. The timing of discontinuation and postoperative restart of antithrombotic or anticoagulant therapy must be carefully planned and should always be evaluated against the risks of bleeding and cardiac events. An interdisciplinary approach to the perioperative coagulation management involving the surgeons, anesthesiologists, cardiologists, and hematologists may sometimes be required. Patient-specific factors (e.g., age, renal function, vascular and cardiac comorbidities) as well as the surgical factors (urgency, type, risk of bleeding) must be carefully evaluated for individualized risk assessment.[79]

For this reason, we provide only a summary of current antiplatelet and anticoagulant drugs (Tables 64.2 and 64.3). In general, arthroplasties are considered as having a moderate risk of bleeding, whereas vertebrospinal surgery is associated with a high risk of bleeding.[81] In a brief and simplified summary for both types of operations, it is recommended that aspirin should be discontinued 5 days before surgery and until 7 days after surgery in patients with a low- to moderate cardiovascular risk (e.g., in patients taking aspirin as a primary prophylaxis). In patients with a high cardiovascular risk (e.g., patients with known coronary artery disease but an acute coronary syndrome >12 months preoperatively, drug-eluting stent >6 months, bare-metal stent >1 month, cardiac bypass surgery >6 weeks), aspirin can be continued during arthroplasty surgery. However, additional antiplatelet drugs should be discontinued according to their pharmacology and the renal function of the patient. For vertebrospinal surgery, it is advised that both drugs of a dual antiplatelet therapy are adequately stopped. Elective orthopedic surgery is not recommended without optimization in patients with a very high cardiovascular risk (acute coronary syndrome <12 months preoperatively, drug-eluting stent <6 months, bare-metal stent <1 month, cardiac bypass surgery <6 weeks, cerebrovascular accident <4 weeks); such surgery should be delayed when possible.[81,83-85]

Similar to patients on antiplatelet therapy, the management of patients under direct oral anticoagulant drugs or vitamin K antagonists also requires consideration of the individual risk of thromboembolic events balanced against the bleeding risk of surgery. Appropriate use of direct oral anticoagulants is particularly important with respect to regional anesthesia in orthopedic patients.[86] The recommendations of the timing of the preoperative interruption of such treatment is somewhat different in Europe (Table 64.4A) and the United States (Table 64.4B).[80,82,87-89] More recently, the American Society of Regional Anesthesia and Pain Medicine (ASRA) in conjunction with the European Society of Anaesthesiology convened a Consensus Conference on Regional Anesthesia and Anticoagulation that updated the available data, representing the collective experience of recognized experts in the field of neuraxial anesthesia and anticoagulation.[89] These guidelines provide a comprehensive summary of evidence-based reviews, but emphasize that the decision to perform spinal or epidural anesthesia and the timing of catheter removal in a patient receiving antithrombotic therapy should be made on an individual basis, weighing the risks of spinal hematoma with the benefits of regional anesthesia for each individual.

PULMONARY, RENAL, HEMATOLOGIC, ENDOCRINE DISEASES, AND NUTRITIONAL STATUS

While cardiac diseases may be the most important considerations determining the overall outcome in high-risk orthopedic patients, other comorbidities such as pulmonary, renal, hematologic, endocrine, and nutritional diseases must also be examined during the preoperative evaluation of orthopedic patients. Although many studies examined postoperative pulmonary complications after noncardiothoracic surgery, they mainly focused on vascular, abdominal, or general surgical patients, and few studies focused on orthopedic surgery cases.[90] In one such orthopedic study, patients suffering from chronic obstructive pulmonary disease who underwent total hip replacement were found to have a longer hospital length of stay, were more likely to be discharged to an extended-care facility, and were at a significantly increased risk for any other complication such as mortality, myocardial infarction, pneumonia, and septic shock.[91] Another study in patients undergoing hip or knee replacements also reported a higher postoperative complication rate in patients with obstructive sleep apnea.[92] In addition, since spine surgery in the prone position is accompanied by a decreased respiratory compliance,[93,94] patients after major spine surgery are at increased risk of postoperative pulmonary complications. Therefore, a thorough pulmonary evaluation and physical examination, including a detailed history, and subsequent medical optimization are critical steps in the preoperative management of orthopedic patients.[95] In selected patients, additional investigations such as chest radiography, spirometry, and assessments of arterial blood gases, albumin levels (OR for pulmonary complications of 2.53 with an albumin level <3.5 g/dL), and BUN (OR 4.81 with a BUN level >7.5 mmol/L) should be considered.[96] In patients scheduled for major scoliosis operations, preoperative fluoroscopy or magnetic resonance imaging to evaluate diaphragm and chest wall movements and preoperative pulmonary function testing might be indicated.[97] The risk of postoperative pulmonary complications can also be estimated with easy-to-use risk scores.[98,99] A strong body of evidence suggests that lung expansion therapy, such as incentive spirometry or deep breathing exercises, can reduce postoperative pulmonary risk.

Today, with medical advancements leading to improved survival and function, an increasing number of patients with chronic kidney disease present for elective orthopedic surgery.[100] There is some discrepancy in the literature with respect to outcome of elective orthopedic surgery in patients with end-stage renal disease (ESRD). Two large retrospective studies failed to show an increased incidence of surgical site infections, thromboembolic events, and 90-day mortality in patients with ESRD undergoing hip replacement surgery.[101,102] Other investigators found higher rates of postoperative complications such as cardiovascular, pulmonary, infectious, and thromboembolic events as well as an increased readmission and mortality rate in patients with ESRD who underwent joint replacement surgery.[103,104] The main concerns for the anesthesiologist in these patients include timing of preoperative and postoperative dialysis to avoid hypervolemia, hyperkalemia, and acidosis; cardiovascular assessment and blood pressure control; electrolyte management, anemia, drug metabolism, and the balance between thromboembolic complications and higher bleeding risk, both of which can be increased in patients with ESRD. The pathophysiology of bone disease represents another important factor to consider preoperatively, since both low and high abnormal bone turnover contribute to the poor bone strength in these patients. Poor bone quality could lead to challenging surgical conditions requiring the use of locking plates or screws, cement fixation, and less rigorous postoperative ambulation, all of which potentially contribute to an increased rate of postoperative complications.[100]

Fig. 64.4 **Proposed algorithm for the detection, evaluation, and management of preoperative anemia.** *SF,* Serum ferritin; *TSAT, transferrin saturation.* (With permission from Goodnough LT, Maniatis A, Earnshaw P, et al. Detection, evaluation, and management of preoperative anaemia in the elective orthopaedic surgical patient: NATA guidelines. *Br J Anaesth.* 2011;106(1):13–22.)

The overall incidence of anemia in the general population increases with age and is estimated to be 10% to 11% in the older adult aged 65 years or older. Until recently, anemia in older adults was often viewed simply as an abnormal laboratory test value with limited consequences. But today, substantial evidence in the literature reveals that previously undiagnosed anemia is common in elective orthopedic patients, and importantly is associated with increased likelihood of blood transfusion and increased perioperative morbidity and mortality.[105] The preoperative evaluation of anemia should, therefore, include considerations to optimize the endogenous red blood cell mass through targeted stimulation of erythropoiesis and treatment of modifiable underlying disorders.[106] Efforts should be made to diagnose and start appropriate treatment of preoperative anemia and minimize perioperative blood loss. This can be achieved through vigilant adherence to protocols including the measurement of hemoglobin, serum ferritin, transferrin saturation, transferrin receptor index, reticulocyte hemoglobin, vitamin B_{12}, folic acid, serum creatinine, and glomerular filtration rate starting as early as 28 days before surgery (Fig. 64.4).[105,106] Implementation of such anemia prevention and management in elective orthopedic patients can improve patient safety and outcomes. The preoperative administration of iron carboxymaltose in anemic patients undergoing major orthopedic surgery resulted in a significant decrease in postoperative infectious complications from 12.0% to 7.9%. Moreover, hospital length of stay was shortened by 1 day.[107]

In addition to the well-recognized risks of antiplatelet and anticoagulant therapy discussed earlier, some orthopedic patients present with impaired primary hemostasis. Since the management of impaired primary hemostasis is no different in orthopedic surgery than in other surgical fields with

TABLE 64.5 Questionnaire for the Detection of an Increased Risk of Bleeding

1. Have you ever experienced strong nose bleeding without prior reason?
2. Did you ever have—without trauma—"blue spots" (hematomas) or "small bleedings" (on the torso or other unusual regions of the body)?
3. Have your gums ever bled for no apparent reason?
4. How often do you have bleedings or "blue spots" (hematomas): 1 to 2 times a week or more often?
5. Do you have the impression that you have prolonged bleedings after minor wounds (e.g., razor cuts)?
6. Did you have prolonged or severe bleedings after or during operations (e.g., tonsillectomy, appendectomy, or during labor)?
7. Did you ever have prolonged or severe bleedings after a tooth extraction?
8. Did you ever receive blood transfusions or other blood products during an operation? If so, please define the operation(s):
9. Is there a history of bleeding disorders in your family?
10. Do you take analgesic drugs or drugs against rheumatic disease? If so, please specify:
11. Do you take other drugs? If so, please specify:
12. Do you have the impression that you have prolonged menstruation (>7 days) and/or a high frequency of tampon change?

From Koscielny J, Ziemer S, Radtke H, et al. A practical concept for preoperative identification of patients with impaired primary hemostasis. *Clin Appl Thromb Hemost*. 2004;10(3):195–204.

associated bleeding risks, such as neurosurgery, we will only briefly summarize here some relevant ideas. Based on robust evidence in the literature, it is recommended that patients with an increased risk of bleeding complications are identified using a standardized questionnaire and, only if indicated, the measurement of platelet count, prothrombin time, activated partial thromboplastin time, PFA-100 platelet function analyzer test, and von Willebrand factor (Table 64.5).[108,109]

Finally, endocrine and nutritional aspects also have an impact on outcome in orthopedic surgery. For severely obese patients, spine surgery is associated with decreased quality of preoperative and intraoperative imaging, surgical limitations due to inadequate operative exposure, increased anesthetic risk such as esophageal reflux and ventilation-perfusion mismatches, and an increased risk of perioperative complications such as wound infection, increased blood loss, venous thrombosis, pneumonia, and nerve injuries as a result of positioning difficulties.[110,111] Conversely, malnutrition is also associated with increased pulmonary risk, increased risk of surgical site infection, and poor surgical outcomes both in spinal and arthroplastic surgery.[90,112,113] Screening for malnutrition in orthopedic surgery includes the measurement of body mass index, anthropometric measurements such as calf or arm muscle circumference, and triceps skinfold, and the determination of serologic laboratory values such as total lymphocyte count (<1500 cells/mm^3), serum albumin (<3.5 g/dL), prealbumin (<16 mg/dL), transferrin (<200 mg/dL), and zinc levels (<66-95 μg/dL).[112] Various scoring systems have been used to detect malnutrition in orthopedic surgery. The Mini Nutritional Assessment is a simple and effective tool for identifying patients at severe nutritional risk.[113,114] While routine enteral or parenteral nutrition does not reduce perioperative risks, patients with severe malnutrition should undergo nutritional assessment by a dietician prior to surgery. The risks and benefits of delaying elective surgery until the nutritional status has improved should be discussed with the patient. Similarly, delaying elective orthopedic surgery in patients with diabetes mellitus with an increased level of hemoglobin A_{1C} (>7%) until after a better glycemic control has been obtained may reduce risk of surgical wound infection and improve outcome.

COMPLICATIONS AND OUTCOME

A very interesting study in more than 100,000 patients identified the determinants of 30-day postoperative mortality and long-term survival after major surgery exemplified by eight common operations, one being total hip replacement.[115] These authors found in a sample size of 12,184 patients undergoing total hip replacement a 30-day mortality rate of 1% and a mortality rate at any time during an average follow-up time of 8 years of 20%, compared with a 30-day mortality rate of 3% and 36% during the 8-year follow up in the whole study population. After a 10-year follow up, the survival rate in the hip replacement surgery patients was still almost 75%. The main complications in hip replacement surgery were urinary tract infection, deep vein thrombosis (DVT), pneumonia, superficial wound infection, deep wound infection, prosthesis failure, pulmonary embolism, myocardial infarction, and peripheral nerve injury. With the presence of any of these complications, the 30-day mortality rate increased from 1% to 6.4%. The occurrence of a postoperative pneumonia increased the 30-day mortality rate to 16.4% and the 5-year mortality rate to 62.7%, and the occurrence of a perioperative myocardial infarction increased the 30-day mortality rate to 29.2% and the 5-year mortality rate to 52.1%.[115] Given these high numbers of adverse outcomes after the occurrence of complications in total joint arthroplasty patients, every effort must be made during the preoperative evaluation to detect patients at risk, to treat potential underlying conditions, and to optimize the health status of patients. Preoperative medical assessment is an important part of the surgical plan. Identifying and treating modifiable risk factors in the preoperative setting can decrease the risk of surgical complications. A standard protocol that involves a multidisciplinary approach to patients in the preoperative, operative, and postoperative periods may ultimately lead to better outcomes and reduced costs.[116]

Special Considerations for Conditions Leading to Orthopedic Surgery

OSTEOARTHRITIS

OA is a degenerative joint disease characterized by articular cartilage loss and osteophyte formation, most often in the hands, knees, hips, feet, and spine. Symptoms include joint pain, which is typically worse with activity, and decreased range of motion. OA is one of the most common causes of chronic pain and disability among older individuals and is the most common reason that patients present for total knee and hip replacement surgery (USBJI). After age, the most important risk factors for OA include obesity and joint trauma or malalignment.

Although OA has no systemic manifestations, medical comorbidities such as cardiac disease and diabetes are common in these patients, and the combination of OA with one of these chronic conditions is associated with a greater degree of physical activity limitation.[117] Preoperative evaluation should take this into account. Patients with chronic pain related to OA, especially those with chronic opioid use, may benefit from a multimodal perioperative analgesic regimen. Patients who frequently take nonsteroidal antiinflammatory drugs (NSAIDs) should be questioned about symptoms of peptic ulcer disease and gastroesophageal reflux. Extra care should be taken when positioning these patients for surgery, being mindful of painful, stiff joints, and existing orthopedic hardware. Severe OA of the cervical spine may affect airway management, whereas severe disease of the thoracic or lumbar spine may make neuraxial techniques more challenging.

RHEUMATOID ARTHRITIS

Rheumatoid arthritis (RA) is an autoimmune inflammatory disease that affects the joints and often other organ systems. It affects approximately 1% of the population in developed nations, is twice as common in women as in men, and most often presents between 60 and 80 years of age.[118] Most patients have detectable autoantibodies such as rheumatoid factor and anticitrullinated protein antibody. Articular manifestations include synovial inflammation and hypertrophy and destruction of cartilage and bone. This presents clinically as painful joint swelling, stiffness, and progressive deformity. In contrast to OA, the pain and stiffness of RA are typically worse after periods of rest and improve with activity. RA most commonly affects the small joints of the hands and feet in a symmetric fashion but may progress to involve larger joints and atypical joints such as the temporomandibular and cricoarytenoid joints. Cervical spine involvement occurs in up to 80% of RA patients. Because RA is a systemic disease, anesthetic considerations can be complex (Table 64.6).

Similar to patients with OA, patients with RA require careful attention to positioning for surgery, especially if cervical spine disease is suspected. Cervical instability is common in RA, affecting up to 61% of RA patients undergoing elective total joint replacement in one study.[119] Instability may result from atlantoaxial or subaxial subluxation, and places the patient at risk for spinal cord compression if the neck is malpositioned (Fig. 64.5). No guidelines exist for preoperative cervical spine evaluation in RA patients. Certainly, patients should be questioned about neck range of motion and any symptoms of pain or radiculopathy. However, significant cervical disease may exist in the absence of symptoms. Radiography of the cervical spine may be considered, and if obtained should include lateral views in flexion and extension, frontal view of the entire cervical spine, and frontal open-mouth odontoid view. If the distance between the posterior border of the odontoid process and the anterior aspect of the posterior arch of C1 is less than 14 mm, a degree of spinal cord compression is likely present (Fig. 64.6).[120]

TABLE 64.6 Anesthetic Considerations for Patients With Rheumatoid Arthritis

Airway	Limited TMJ movement Narrow glottis opening
Cervical spine	Atlantoaxial instability
Cardiac	Pericarditis Pericardial fluid with tamponade physiology
Eyes	Sjögren syndrome
Gastrointestinal	Gastric ulcers secondary to ASA or steroids
Pulmonary	Diffuse interstitial fibrosis
Renal	Renal insufficiency secondary to NSAIDs

ASA, acetylsalicylic acid; *NSAIDs*, nonsteroidal antiinflammatory drugs; *TMJ*, temporomandibular joint

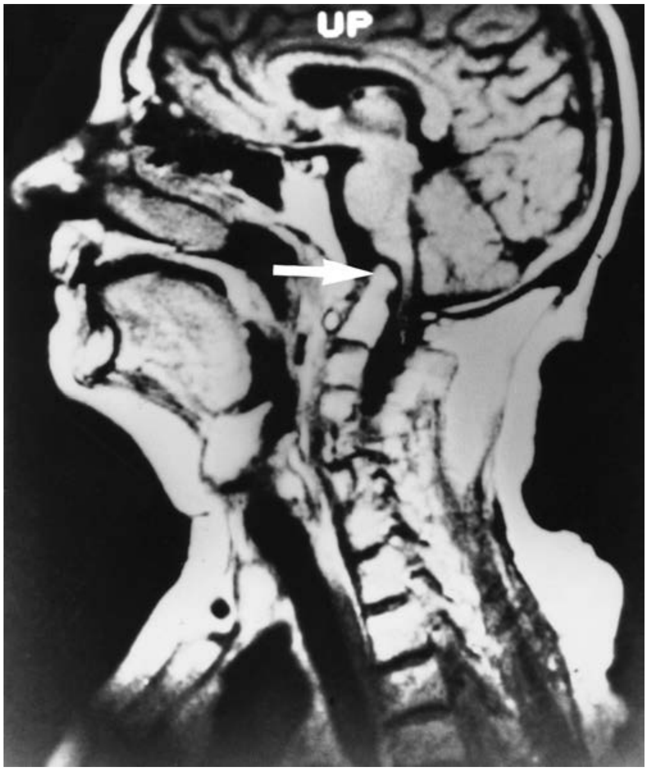

Fig. 64.5 Magnetic resonance image of a patient with advanced rheumatoid arthritis shows invagination of the odontoid process of C2 *(arrow)* through the foramen magnum, compressing the brainstem. Notice the degeneration of C4 and C5, a common problem in rheumatoid arthritis.

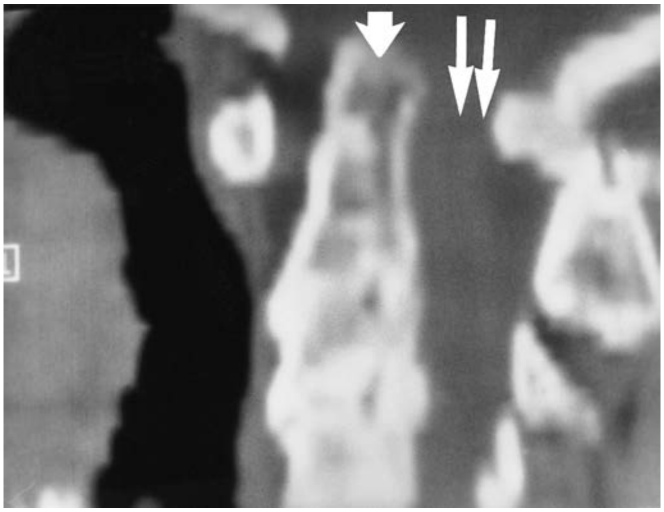

Fig. 64.6 Computed tomography scan of the neck shows moderate subluxation of C1 and C2. The odontoid *(single arrow)* tends to compress the spinal cord *(double arrow)* against the posterior arch of C1, especially during neck flexion.

If cervical instability is suspected, airway management should proceed cautiously with minimal manipulation of the neck. Even in the absence of cervical spine disease, patients with RA may present with challenging airways due to temporomandibular joint disease that limits mouth opening or cricoarytenoid joint stiffness that impedes passage of the endotracheal tube. Fiberoptic intubation or regional techniques with a natural airway may be attractive options for these patients.

Extraarticular manifestations of RA are common and are associated with increased morbidity and mortality, primarily related to cardiovascular disease.[121] The systemic inflammation caused by RA contributes to premature atherosclerosis. As a result, the risk of myocardial infarction, congestive heart failure, and stroke is twice as high in patients with RA compared to individuals without RA.[122] Pericarditis is the most common cardiac manifestation of RA but rarely results in clinically significant disease. Although RA has not been shown to be an independent risk factor for perioperative mortality or adverse cardiovascular events,[123] thorough preoperative cardiovascular risk assessment is warranted in these patients. Pulmonary involvement of RA is also relatively common in the form of pleural effusions and interstitial lung disease. Severity varies from subclinical to, rarely, severe. Preoperative chest radiography or pulmonary function tests may be informative when significant pulmonary disease is suspected. Other extraarticular manifestations of RA include subcutaneous rheumatoid nodules on bony prominences or extensor surfaces, small- to medium-vessel vasculitis, and hematologic abnormalities such as anemia and thrombocytosis.

Treatment for RA focuses on early initiation of disease-modifying antirheumatic drug (DMARD) therapy, with the goal of achieving clinical and radiographic disease remission. In addition to conventional DMARDs such as methotrexate, hydroxychloroquine, sulfasalazine, and leflunomide, many patients benefit from treatment with an ever-growing arsenal of biologic agents that use monoclonal antibodies or receptor proteins to inhibit inflammatory cytokines or cell lines. A notable risk with DMARDs is immunosuppression and possibly impaired wound healing. Current evidence supports continuation of methotrexate perioperatively but is inconclusive about the effect of other agents on perioperative infection and wound complication rates. A conservative approach is to hold biologic agents for at least one dosage cycle prior to surgery and resume once wound healing has progressed.[124] In each case, the benefit of improved immune function and wound healing must be balanced with the risk of disease flare, and it may be appropriate to continue DMARDs perioperatively for some patients. This plan should be developed with input from the patient's rheumatologist and surgeon. Patients taking corticosteroids for RA may require stress-dose steroids perioperatively. They should be questioned about symptoms of gastroesophageal reflux, as should patients who take NSAIDs chronically.

ANKYLOSING SPONDYLITIS

Ankylosing spondylitis is an autoimmune seronegative spondyloarthropathy that typically affects the spine and sacroiliac joints but may involve peripheral joints as well. It affects men disproportionately and most often presents between the ages of 20 to 30 years. Inflammation in affected joints leads to formation of fibrocartilage and ectopic bone, and ultimately fusion of the joint. The classic "bamboo spine" appearance seen radiographically in advanced disease is caused by ossification of the vertebral ligaments. This in combination with osteoporotic compression fractures can result in rigid kyphosis that may require surgical correction (Fig. 64.7).

Despite their rigidity, the spines of patients with advanced ankylosing spondylitis are also quite fragile. Vertebral fractures may occur spontaneously or with minimal trauma; the cervical spine is a common site.[125] Obviously, this has serious implications for intraoperative positioning and airway management. Neck range of motion and preexisting neurologic deficits should be thoroughly evaluated preoperatively, and adequate neck support must be provided at all times to avoid hyperextension. Cervical kyphosis may make direct laryngoscopy difficult or impossible, and temporomandibular joint disease may limit mouth opening. Awake fiberoptic intubation may be the safest option in patients with severe cervical disease, as it allows for spontaneous ventilation as well as neurologic monitoring throughout intubation. Video laryngoscopy has also been used successfully in ankylosing spondylitis patients.[126] The laryngeal mask airway (LMA) may be useful in cases where endotracheal intubation is not required, or as a bridge to intubation if an intubating LMA is used.[127]

The spinal pathology of ankylosing spondylitis may also result in difficulty with neuraxial techniques. Furthermore, the incidence of epidural hematoma after neuraxial anesthesia is higher in ankylosing spondylitis patients than in the general population. This may be related to an increased incidence of traumatic needle placement, the prevalence of NSAID use among ankylosing spondylitis patients, or narrowing of the

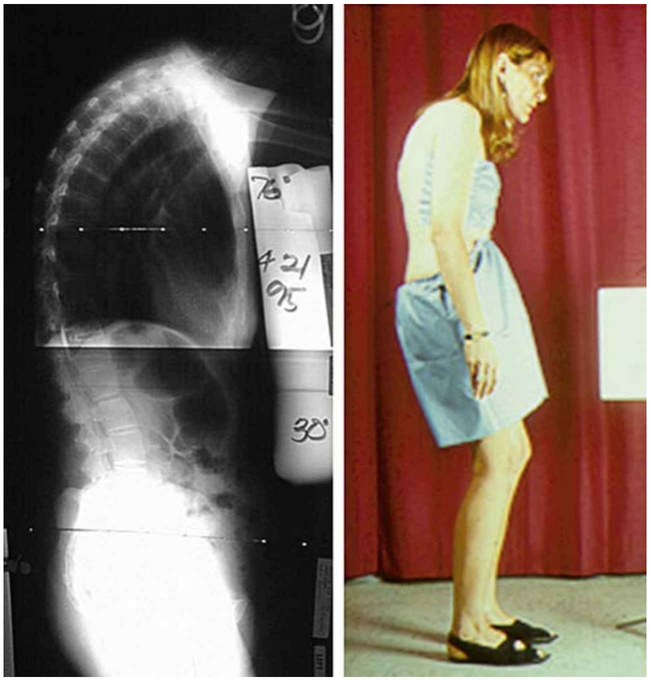

Fig. 64.7 **Patient with ankylosing spondylitis, exhibiting significant kyphosis of the spine.** Note significant kyphosis in the lateral radiograph.

epidural space that makes symptomatic spinal cord compression more likely when a hematoma occurs.[128] If neuraxial anesthesia is indicated, ultrasound or fluoroscopic guidance may facilitate placement. Subsequently, vigilance should be maintained for symptoms of epidural hematoma.

Extraarticular manifestations of ankylosing spondylitis occur more often in patients with severe disease. Inflammation and fibrosis of the ascending aorta and aortic root can lead to aortic insufficiency, and extension to the conduction system may result in heart block or supraventricular arrhythmias. The prevalence of aortic insufficiency and conduction abnormalities in ankylosing spondylitis patients increases with duration of disease, occurring in 3.5% and 2.7%, respectively, after 15 years and 10% and 8.5%, respectively, after 30 years.[129] As in RA, patients with ankylosing spondylitis also have an elevated risk of atherosclerosis.[130] Pulmonary manifestations of ankylosing spondylitis include restrictive lung disease due to kyphosis and chest wall rigidity. Pulmonary fibrosis may be seen in advanced disease. The duration and severity of disease should inform the extent of preoperative cardiopulmonary evaluation, which might include electrocardiography, echocardiography, and/or pulmonary function testing.

ACHONDROPLASIA

Achondroplasia is characterized by disproportionately short stature, lumbar lordosis, large head, midface hypoplasia, short hands, and normal cognitive development. Its incidence is estimated at 1 in 10,000 to 1 in 30,000. Although it is an autosomal-dominant condition, the majority of cases occur as a result of a de novo genetic mutation.[131] Patients with achondroplasia may present for orthopedic surgery as children or adults for correction of associated abnormalities such as tibial bowing and spinal stenosis.

The primary anesthetic challenge in patients with achondroplasia is airway management. Midface hypoplasia with a pharynx that is small in proportion to the tonsils, adenoids, and tongue makes these patients prone to upper airway obstruction and may hinder direct laryngoscopy. A flat nasal bridge and large mandible may make it difficult to obtain an adequate seal for mask ventilation. Hyperextension of the neck should be avoided due to the possibility of foramen magnum stenosis. Video laryngoscopy or fiberoptic intubation should be considered for these patients, and a range of endotracheal tube sizes should be on hand, as many patients require a size smaller than what would be expected based on age. Other anesthetic considerations in patients with achondroplasia include the possibility of difficult neuraxial anesthesia due to spinal deformity or stenosis, and cardiopulmonary sequelae such as restrictive lung disease, central and obstructive sleep apnea, and resultant pulmonary hypertension.[132] Preoperative echocardiogram to assess for pulmonary hypertension should be considered prior to major surgery.

Orthopedic Procedures in Children with Special Conditions

The anesthetic management of children undergoing orthopedic surgery is beyond the scope of this chapter. However, a number of musculoskeletal conditions will require multiple orthopedic surgeries during childhood and may pose special challenges to the anesthesiologist.

JUVENILE IDIOPATHIC ARTHRITIS

Juvenile idiopathic arthritis (JIA) is the most common rheumatic disease in children. It is characterized by chronic arthritis with onset before the age of 16 and encompasses five distinct subtypes as described below. JIA may be seropositive or seronegative, is twice as common in girls as in boys, and may persist into adulthood.[133]

1. Oligoarticular JIA: Involves fewer than 5 joints. Accounts for at least 50% of JIA. Often has an indolent presentation.
2. Polyarticular JIA: Involves 5 or more joints. Accounts for 25% to 40% of JIA. Usually requires DMARD therapy.
3. Psoriatic JIA: Arthritis with psoriasis.
4. Enthesitis-related JIA: Affects the spine, sacroiliac joints, and points of tendon attachment to bone.
5. Systemic-onset JIA: Presents with daily fever and rash.

As in adult arthritis, special care should be paid to joint range of motion and intraoperative positioning for patients with JIA. The cervical spine and temporomandibular joints may be affected in JIA, especially in the polyarticular subtype, and appropriate precautions should be taken when planning for airway management. In children, awake fiberoptic intubation may not be a feasible option. In this case, fiberoptic intubation may be performed asleep with spontaneous ventilation maintained throughout induction. Common extraarticular manifestations of JIA include growth abnormalities and uveitis. Pericarditis and pleural effusions sometimes occur in systemic-onset JIA. Medical therapies for JIA are similar to those for RA, including conventional DMARDs and biologics, which raise similar considerations for perioperative risks and management.

OSTEOGENESIS IMPERFECTA

Osteogenesis imperfecta encompasses a group of heritable bone dysplasias caused by mutations in collagen-related genes. It occurs with an incidence of 1 in 10,000 and is characterized by bone fragility resulting in deformity and susceptibility to fracture. Secondary features include short stature, blue or gray sclerae, conductive hearing loss, abnormal dentin resulting in weak and discolored teeth, foramen magnum stenosis, cardiac valvular abnormalities, and bleeding diathesis. Although the most severe subtype of osteogenesis imperfecta results in perinatal death, the life expectancy for patients with other subtypes extends well into adulthood.[134]

Patients with osteogenesis imperfecta may require a number of orthopedic surgeries such as fracture fixation, intramedullary rodding for correction of long-bone deformities, spinal fusion for scoliosis, and joint replacement. Anesthetic management may be challenging (Table 64.7). Utmost care must be taken to avoid iatrogenic fracture when positioning these patients for surgery. The area under the blood pressure cuff should be padded or an arterial line placed to minimize the risk of humeral fracture. Tourniquets must be managed

TABLE 64.7 Anesthetic Considerations for Patients With Osteogenesis Imperfecta

Airway	Risk for fractures of the mandible, maxillary surface, and cervical spine
Bleeding	Platelet abnormalities
Cardiac	Congenital and valvular heart disease Cystic degeneration of proximal aorta
Eyes	Exophthalmos Risks associated with prone positioning
Hyperthermia	Malignant hyperthermia, hydration, possible cooling
Positioning	Risk for fractures
Pulmonary	Kyphoscoliosis, restrictive lung disease
Regional anesthesia	Fractures, intraosseous injections

with similar care. Succinylcholine should be avoided in patients with osteogenesis imperfecta because of the risk of fracture upon fasciculation. Airway management must be performed gently with minimal manipulation of the head and neck to avoid cervical, facial, and dental fractures. Fiberoptic intubation may facilitate this. Neuraxial techniques may be considered in patients with normal platelet function but may be challenging due to scoliosis. Care must be taken to avoid needle trauma to bone and intraosseous injection.

Several extraskeletal manifestations of osteogenesis imperfecta are relevant to the anesthesiologist. The same collagen abnormalities that affect bone may also affect the cardiac valves and aorta, resulting in regurgitant lesions, aortic root dilation, and even aortic dissection. Restrictive or obstructive lung disease may be present as a result of kyphoscoliosis or chest wall deformity. In fact, pulmonary complications are the leading cause of death in osteogenesis imperfecta. Preoperative echocardiography or pulmonary function testing should be considered if a murmur or symptoms of cardiopulmonary disease are noted. Patients with osteogenesis imperfecta are at risk for increased surgical bleeding due to platelet dysfunction and vessel fragility. Patients should be evaluated for coagulopathy preoperatively, and if necessary, treated with desmopressin (DDAVP) or platelet transfusion.

A link between osteogenesis imperfecta and malignant hyperthermia (MH) has been suggested in the literature, but the evidence for this association is weak. Intraoperative hyperthermia and metabolic acidosis have been observed in patients with osteogenesis imperfecta, but in most cases, this was not associated with other signs of hypermetabolism and resolved with cooling measures alone. There is a lack of consensus on the use of MH-triggering agents in patients with osteogenesis imperfecta. The most conservative approach is to administer a nontriggering anesthetic, but in cases where this presents a significant challenge (as in an uncooperative child with difficult intravenous access), use of volatile anesthetics may be considered. In all cases, patients should be carefully monitored for hyperthermia and acidosis, and appropriate treatment modalities should be readily available.[135]

CEREBRAL PALSY

Cerebral palsy is the most prevalent cause of persistent motor impairment in children, affecting 1 to 2 of every 1000 live births in developed countries. It is caused by antenatal or perinatal injury to the developing brain and is characterized by nonprogressive abnormalities of movement and posture such as spasticity, ataxia, and dyskinesias. The motor deficit may be mild or severe, isolated, or accompanied by other abnormalities including cognitive impairment, speech disorders, and seizures. Patients with cerebral palsy often require multiple orthopedic surgeries such as soft tissue release and tendon lengthening for contractures, osteotomies for hip deformities, and spinal fusion for scoliosis.

Anesthetic management of patients with cerebral palsy requires consideration of the psychosocial as well as medical aspects of their condition.[136] Communication may be challenging due to cognitive delay, behavioral problems, or speech difficulties, necessitating special accommodations and involvement of parents or caretakers in perioperative interactions. It is important to remember that speech impairment does not necessarily imply cognitive impairment. In patients with seizures, antiepileptic drugs should be continued perioperatively and inquiry made as to the frequency and semiology of seizures. Gastroesophageal reflux is common in cerebral palsy and may be an indication for rapid sequence intubation. Bulbar dysfunction can further contribute to chronic aspiration and feeding difficulties that sometimes requires gastrostomy tube placement. Chronic aspiration, recurrent respiratory infections, and restrictive deficits due to kyphoscoliosis result in significant pulmonary morbidity in these patients. Airway management may be challenging due to cervical kyphosis or dystonia, temporomandibular joint dysfunction, or poor dentition. Patients with cerebral palsy have a lower minimum alveolar concentration (MAC) than normal controls and may be prone to intraoperative hypothermia due to hypothalamic dysfunction. An association between cerebral palsy and latex allergy has been noted, likely related to the multiple surgical procedures many of these patients undergo.[137]

SPINA BIFIDA

Spina bifida is a term that is broadly applied to a diverse group of congenital malformations of the spine and spinal cord. Embryologically, these conditions result from a failure of fusion of the neural tube. Discussion of spina bifida is complicated by a lack of consistency in terminology and classification, but malformations can be broadly divided into open defects with exposed neural tissue such as myelomeningocele and myeloschisis, and closed defects with a skin covering such as meningocele, tethered cord, and split cord. Open defects are usually associated with a neurologic deficit and are almost always repaired perinatally, or with the advent of fetal surgery, prenatally. Closed defects may have an associated deficit or may be asymptomatic and undiagnosed until adulthood. Cutaneous abnormalities such as a sacral dimple, hemangioma, or tuft of hair may raise suspicion for a closed defect, but these are not always present.[138]

Neurologic abnormalities associated with spina bifida include motor and sensory deficits below the level of the defect, Chiari II malformation, hydrocephalus, and neurogenic bladder. Patients with spina bifida may present for orthopedic surgery for correction of congenital or acquired limb deformities such as clubfoot or hip dislocation, spinal fusion for scoliosis, or release of contractures. Patients with tethered cord syndrome may present for cord release as children or adults. As in cerebral palsy, repeated surgical exposures in spina bifida patients result in an increased incidence of latex allergy.

The most significant anesthetic implications of spina bifida are related to neuraxial anesthesia. Whether or not the patient has undergone corrective spinal surgery, anatomic abnormalities in the spine can lead to an increased risk of inadvertent dural puncture, failed block, and neurologic injury. For example, the ligamentum flavum may be malformed or absent, precluding identification of the epidural space with loss-of-resistance technique. The epidural space may be abnormal or nonexistent in patients who have undergone prior surgical repair. Cord tethering can result in low termination of the spinal cord and posterior placement of neural elements within the spinal canal, increasing the risk of neurologic injury with spinal anesthesia or inadvertent dural puncture. Neuraxial techniques should be approached with extreme caution in patients with tethered cord syndrome, if at all.

If neuraxial anesthesia is indicated in a patient with spina bifida, it should only be attempted if there is a thorough understanding of the patient's spinal anatomy. Magnetic resonance imaging (MRI) of the spine should be obtained to allow for examination of bony and ligamentous defects, the level of termination of the spinal cord, and the presence of masses such as lipoma or syrinx. Needle placement through surgical scars should be avoided, and epidurals should be placed above the level of the spinal defect. Smaller than usual epidural boluses are recommended, as abnormal anatomy might result in more extensive spread. Failed or incomplete block may result in the need for rescue analgesia or conversion to general anesthesia.[139]

DUCHENNE MUSCULAR DYSTROPHY

Duchenne muscular dystrophy (DMD) is an X-linked recessive neuromuscular disorder that occurs in 16 per 100,000 live male births in the United States. Mutations in the dystrophin gene result in muscular degeneration that is progressive and ultimately fatal. Weakness usually begins in early childhood with loss of ambulation by age 8 to 12 years, respiratory insufficiency and cardiomyopathy by the early 20s, and death before age 30 due to pulmonary complications or heart failure. However, with advancements in care, the life expectancy for DMD is improving, and some patients may survive into their 30s or 40s. Glucocorticoids are the mainstay of treatment for DMD. Patients with DMD may present for orthopedic surgery to correct lower extremity deformity, scoliosis, or contractures. These patients are also prone to osteoporosis with increased risk of fractures that may require operative fixation.

Patients with DMD have an elevated risk of perioperative cardiac and respiratory decompensation and should undergo a thorough cardiopulmonary evaluation prior to surgery. Depending on the stage of their disease, this may include an electrocardiogram, echocardiogram, and pulmonary function testing. Extubation to noninvasive positive pressure ventilation is recommended for patients with a forced vital capacity (FVC) less than 50% predicted, and essential for those with an FVC less than 30% predicted. Aggressive postoperative pulmonary hygiene should be strongly encouraged.[140]

Use of succinylcholine is strictly contraindicated in patients with DMD because of the risk of acute rhabdomyolysis. Inhaled anesthetics are also best avoided, as they have been implicated in cases of perioperative metabolic reactions ranging from intraoperative hyperthermia and tachycardia to rhabdomyolysis to hyperkalemic arrest. The mechanism of these reactions is thought to be distinct from that of MH.[141] Patients with DMD have both a delayed onset time and prolonged recovery time with nondepolarizing neuromuscular blockers, which places them at risk for residual neuromuscular blockade and recurarization. Quantitative monitoring of neuromuscular blockade is recommended to ensure full reversal. Cholinesterase inhibitors are safe and effective for reversal in these patients, and sugammadex has been used successfully as well.[142]

ARTHROGRYPOSIS MULTIPLEX CONGENITA

Arthrogryposis multiplex congenita is characterized by congenital nonprogressive contractures affecting at least two different areas of the body. It occurs with an incidence of about 1 in 4300 to 5100 live births. Arthrogryposis multiplex congenita is not a single disorder, as once thought, but actually encompasses hundreds of conditions with distinct etiologies, both genetic and environmental. A common theme in most of these is decreased fetal movement, which leads to abnormal joint development. Deformity may be limited to the limbs or associated with spine and craniofacial abnormalities. Neurologic dysfunction is present in some cases and portends a less favorable prognosis.[143]

Treatment of arthrogryposis multiplex congenita requires early orthopedic intervention with splinting and surgery to optimize a child's ability to ambulate and perform activities of daily living. The primary anesthetic challenge in arthrogryposis multiplex congenita is airway management, which may be complicated by craniofacial abnormalities such as small mouth opening, high arched palate, or micrognathia, as well as limited cervical range of motion. These patients are at risk of perioperative respiratory complications as a result of restrictive thoracic deformities and increased sensitivity to opioids and neuromuscular blockers. This makes regional and neuraxial anesthesia attractive options, but these techniques may be challenging due to limb contractures, scoliosis, or associated spina bifida.[144]

Two cases of suspected MH have been reported in patients with arthrogryposis multiplex congenita, as well as other cases of perioperative hyperthermia and hypermetabolism without skeletal muscle destruction. As such, succinylcholine should be avoided in these patients, and exposure to volatile anesthetics should be minimized.[135]

Perioperative Management of the Orthopedic Patient

SPECIAL CONSIDERATIONS

In addition to the perioperative cardiovascular, pulmonary, renal, and hepatic considerations described earlier, orthopedic procedures are associated with unique risks and complications related to bone injury, immobilization, and the use of implants and cement material. Bone hemostasis can be difficult, and without antifibrinolytic agents, even primary hip and knee arthroplasties can be associated with considerable bleeding requiring transfusion of blood products. Extensive review of these considerations is beyond the scope of this chapter, but given the rising interest in the literature and its clinical importance, perioperative use of antifibrinolytic agents is summarized below, along with the clinical presentation and management of fat embolism and bone cement implantation syndrome.

Antifibrinolytic Drugs

Blood transfusions are associated with an increased risk of adverse events including mortality, prolonged length of hospitalization, and higher overall costs associated with surgery. Antifibrinolytic agents, such as tranexamic acid (TXA) and epsilon-aminocaproic acid (EACA), bind reversibly to plasminogen by its lysin-binding site, inhibiting its association with fibrin. They also inhibit the proteolytic activity of plasmin. Both TXA and EACA are effective in reducing perioperative blood loss and the need for transfusion and reoperation for bleeding.

Among orthopedic surgeries, the strongest evidence for the use of TXA and EACA is found in multilevel spine surgeries and arthroplasties. Several comprehensive meta-analyses have examined the use of systemic TXA in these procedures. Two meta-analyses studying the use of intravenous TXA in spine surgeries demonstrated significant reductions in intraoperative and postoperative blood loss and allogenic blood transfusion compared with placebo. However, initiation doses (10-20 mg/kg, 100 mg/kg, or 1-2 g) and maintenance doses (1 mg/kg/h, 10 mg/kg/h, and 100 mg/kg/h) were highly variable.[145,146] Similar results with regard to efficacy and safety have been shown with the use of intravenous TXA in TKA and THA. TXA has been shown to reduce total blood loss, postoperative bleeding, and the transfusion rate when given intraoperatively with an intravenous infusion compared to a postoperative administration. A common approach is to administer 10 to 15 mg/kg before the incision, followed by a 1 mg/kg/h infusion during the surgery.[147,148] A recent meta-analysis also demonstrated that TXA resulted in significant reductions in total blood loss and transfusion requirements following total shoulder arthroplasty.[149] The rate of thromboembolic events was not significantly greater when the above dose of TXA was administered in selective patients without contraindications.

Topical administration of TXA, although not a US Food and Drug Administration (FDA)-approved route of administration, has a theoretical safety benefit over intravenous administration. Topical TXA has shown superior efficacy to placebo and similar efficacy (measured as reductions in total blood loss and transfusion rates) to intravenous TXA in TKA and THA. No difference in the rate of thromboembolic events has been demonstrated when comparing topical TXA to placebo or intravenous TXA. The doses of topical TXA used in studies are highly variable and usually range from 1 to 3 g. Thus, a standard topical dose has not yet been established.[150-152]

EACA has also been shown to decrease total blood loss and need for transfusion among patients undergoing spine surgeries.[153] Among TKA and THA patients, however, EACA did not reduce the need for blood transfusion.[154,155] An increased risk of DVT and pulmonary embolism has not been reported following the use of EACA in THA,[154] though sufficient data in TKA or spine surgeries are not yet available. Loading doses (100-150 mg/kg or 5 g) with a continuous infusion ranging from 10 to 15 mg/kg/h during spine surgeries have been used.[153] For THA and TKA, weight-based (12.5-100 mg/kg) and fixed doses (5-10 g) of EACA have been utilized.[154]

Although no increase in the incidence of venous thromboembolism was observed in the above randomized clinical trials, it is important to note that high-risk patients were excluded and none of the studies was adequately powered to detect smaller but clinically relevant differences between treatment groups. Therefore, because of concerns of venous thromboembolism, antifibrinolytic agents are commonly avoided in patients who have any of the following conditions: a history of arterial or venous thromboembolic disease; a recent placement of a cardiac stent; a history of severe ischemic heart disease (NYHA Class III or IV) or myocardial infarction; and history of cerebrovascular accident, renal impairment, or pregnancy. Currently, there is limited data to support the use of EACA in spine surgeries, THA, or TKA, whereas evidence for TXA is more robust. In select patients who are at high risk for transfusion, intravenous or topical TXA should be considered.

Fat Embolism Syndrome

The subclinical form of fat embolism occurs in nearly all patients following long bone or pelvic fractures, as well as after hip or knee replacement surgeries. A clinically significant fat embolism syndrome (FES) is present in up to 30% of these patients.[156,157] An increase in intramedullary pressure and a disruption of the venous sinusoids within the long bones following a fracture or a surgical manipulation such as reaming can result in fat and bone marrow debris entering the venous circulation. The debris lodges in the lung microvasculature, leading to a mechanical obstruction of pulmonary circulation. Free fatty acids released following hydrolysis of fat globules trigger systemic inflammatory response and induce injury to the pulmonary endothelium with an increased capillary leak and increased platelet adhesion with clot formation in the microvasculature. In the presence of intracardiac (patent foramen ovale) or pulmonary shunts, fat particles may also enter the systemic circulation leading to cerebral and cutaneous manifestations.

Symptoms of FES include hypoxemia, respiratory alkalosis, mental status changes, petechial rash (in the conjunctiva, oral mucosa, and skin folds of the neck and axilla), thrombocytopenia, and fat microglobulinemia. The presentation of FES can be gradual, developing between 12 and 72 hours after trauma or surgery. Intraoperatively, FES can also present as a cardiovascular collapse following reaming of long bones, intramedullary insertion of cemented prosthesis, or tourniquet release. Chest radiographs usually show bilateral diffuse infiltrates, particularly in the upper and middle lobes of the lung. MRI of the brain of the patients with significant mental status changes can reveal multiple hyperintensive lesions. Arterial blood gas assessment is useful to determine the degree of hypoxemia.[156] The best preventive management strategy of FES is an early surgical reduction and immobilization of the fracture site. Therapy of FES includes early supportive care with supplemental oxygen and, if necessary, mechanical ventilation to correct hypoxemia, and careful fluid management to prevent worsening of capillary leak. There is currently no evidence supporting the use of steroids, heparin, or dextran in the management of FES.[157] The overall mortality remains high (up to 20%).

Bone-Cement Implantation Syndrome

During arthroplasties, the prosthesis can be attached to the medullary canal of long bones using methyl methacrylate cement or through bone ingrowth. Cemented fixation of the prosthesis can be complicated by bone-cement implantation syndrome (BCIS) that manifests by marked intraoperative hypotension, bronchoconstriction, hypoxia, cardiac arrhythmias, increased pulmonary vascular resistance, right ventricle failure, or even cardiac arrest.[158] Several mechanisms of BCIS have been proposed, including embolization of bone marrow debris to the pulmonary circulation during pressurization of the medullary canal, toxic effects of circulating methyl methacrylate monomer, and release of cytokines and cyclooxygenase products during reaming of the medullary canal, which can induce pulmonary vasoconstriction and formation of microthrombi. Embolization is believed to occur as a result of high intramedullary pressures during cementing. In cemented arthroplasties, intramedullary pressure can peak at 680 mm Hg, compared to less than 100 mm Hg in arthroplasties without the use of cement. The presence of bone marrow debris has, indeed, been documented in the right heart with intraoperative transesophageal echocardiography (TEE) (Figs. 64.8 and 64.9).[159]

Risk factors for this complication include metastatic disease, a previously not instrumented femoral canal (it is thought that the inner surface of the femur becomes smooth and sclerotic once instrumented and cemented, and thus, offers a less permeable surface), a long-stem prosthesis, a THA for pathologic fractures, preexisting pulmonary hypertension and right ventricle failure, and a large quantity of cement used. The hemodynamic consequences of bone marrow embolization may be attenuated through a vigorous pulsatile lavage of the medullary canal and by drilling distal venting holes within the long bones before prosthesis insertion. However, the venting technique can result in significant cement extravasation. Use of noncemented prosthesis should thus be considered in high-risk patients.[160] These patients should be monitored with an arterial catheter and, possibly, also a central venous catheter. Management of BCIS is mainly supportive and includes adequate fluid resuscitation and ventilatory support. The hypotensive events following BCIS may require treatment with potent inotropic and vasopressor agents such as epinephrine.

ORTHOPEDIC TRAUMA

Pelvic Fractures

Pelvic fractures are among the most complicated orthopedic injuries and are associated with a high mortality rate (up to 32% in open fractures). They are typically a result of blunt force trauma, including motorcycle and motor vehicle accidents (60%-80%). The classification of pelvic trauma into minor, moderate, and severe is based on the pelvic ring injury's anatomic classification (Antero-Posterior Compression; Lateral Compression; Vertical Shear; Combined Mechanisms) and more importantly, the hemodynamic status.[161] Patients suffering from traumatic pelvic fractures often have other associated life-threatening injuries (to the head and neck, thoracoabdominal area, and extremities) that need to be taken into consideration during perioperative management.

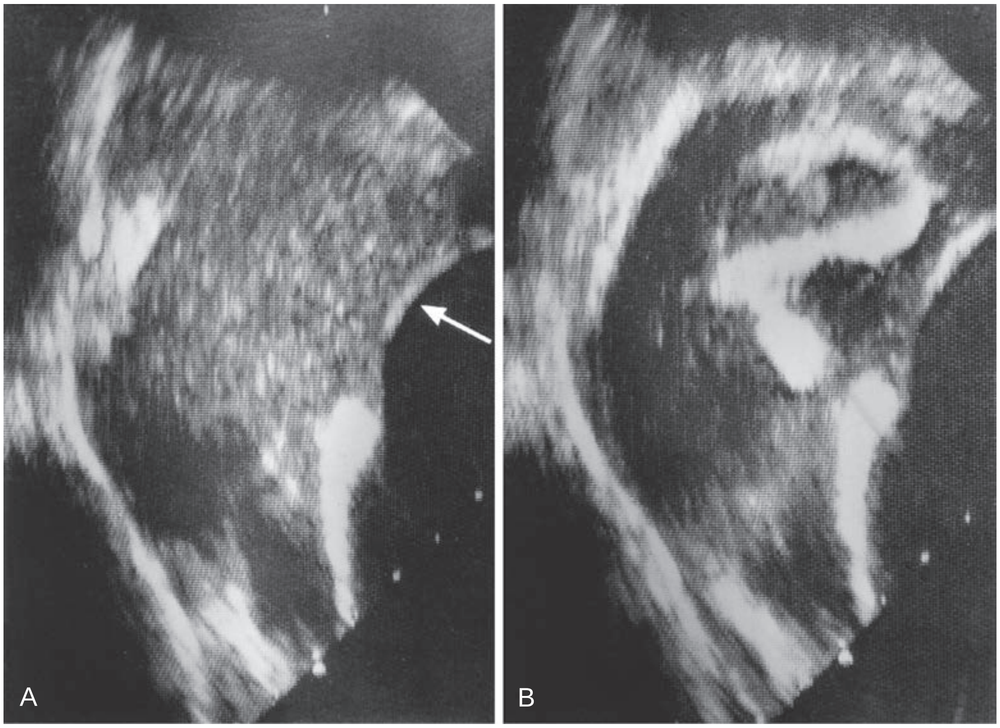

Fig. 64.8 Right atrium during echocardiography. (A) Multiple, small emboli *(arrow)* in the right atrium. (B) Large embolus (7 cm long), which is probably a cast of the femoral vein. (Modified from Christie J, Burnett R, Potts HR, et al. Echocardiography of transatrial embolism during cemented and uncemented hemiarthroplasty of the hip. *J Bone Joint Surg Br*. 1994;76:409–412.)

In addition, pelvic fractures can result in fatal retroperitoneal bleeding.[162] An accompanying blunt chest trauma can produce both cardiac contusion and aortic tear. Preoperative ECG and measurements of cardiac enzymes can help evaluate the extent of myocardial injury. Thorough preoperative neurologic assessment including mental status, motor, and sensory examination is indicated prior to inducing anesthesia. Injuries to the bladder and urethra are also common. Urologic evaluation may be needed before inserting an indwelling catheter. Insertion of chest tubes prior to surgery may also be needed if significant hemothorax or pneumothorax are present. These patients should be considered for a temporary inferior vena cava filter due to a high risk of DVT and pulmonary embolism.

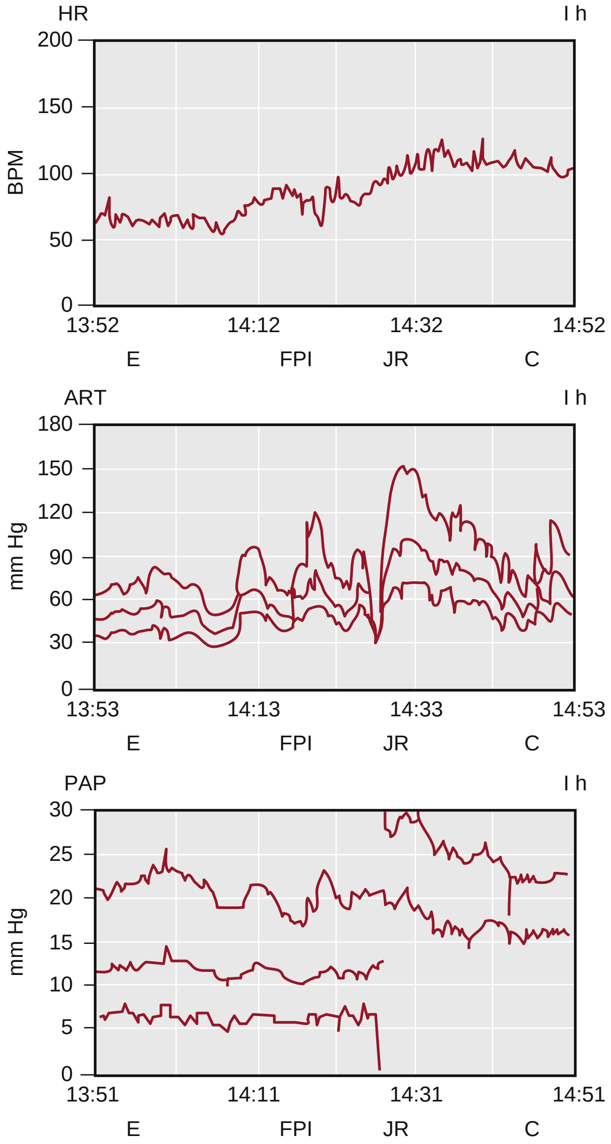

Fig. 64.9 Beats per minute *(BPM)*, intraoperative heart rate *(HR)*, systemic arterial blood pressure *(ART)*, and pulmonary arterial pressure *(PAP)* tracings of a patient undergoing revision total hip arthroplasty. *C,* wound closure; *E,* Induction of epidural anesthesia; *FPI,* insertion of a cemented femoral prosthesis; *JR,* reduction of prosthetic hip joint, producing hypotension with rebound from epinephrine injection. (From Urban MK, Sheppard R, Gordon MA, et al. Right ventricular function during revision total hip arthroplasty. *Anesth Analg*. 1996;82:1225–1229.)

A multidisciplinary approach that includes trauma and orthopedic surgeons, urologists, interventional radiologists, anesthesiologists, and intensive care unit (ICU) physicians is crucial during the immediate management of these patients and should focus on adequate volume resuscitation, achieving hemostasis, and mitigating tissue injuries.[161] As soon as possible after the primary evaluation and stabilization, a comprehensive radiologic workup should be performed. CT is the gold standard with a sensitivity and specificity for bone fractures close to 100%. Initial treatment of pelvic trauma generally involves damage-control resuscitation and application of noninvasive external pelvic compression to stabilize the pelvic ring and decrease the amount of pelvic hemorrhage. Patients with hemodynamic instability should be considered for pre-peritoneal pelvic packing, especially in hospitals with no angiography service. External pelvic fixation provides rigid temporary pelvic ring stability and serves as an adjunct to early bleeding control in hemodynamically unstable pelvic ring disruptions.[161,162] The optimal time for definitive surgical fixation of pelvic ring injuries is within the first week of trauma.

Anesthetic management of patients with pelvic trauma in the operating room can be very challenging. Because of the extent of the surgery, general endotracheal anesthesia with standard or rapid sequence induction based on clinical presentation is indicated. These patients often need an immediate and aggressive resuscitation and, frequently, angiography and embolization of the injured vasculature.[161,163] The primary goal of the rapid resuscitation is to restore blood volume and maintain perfusion to the vital organs, with continuous evaluation of the efficacy of the fluid replacement. Sensitive laboratory markers of tissue ischemia secondary to the acute traumatic hemorrhage include increased serum lactate and base deficit by arterial blood gas analysis.[161] It is important to restore hemoglobin to a level that provides adequate tissue oxygenation (usually considered more than 7-8 g/dL) prior to inducing anesthesia, and to have sufficient amount of blood products available because of the risk for significant intraoperative blood loss. Because of the large intraoperative blood loss and third-spacing of fluids, invasive hemodynamic monitoring, including an arterial line and central venous catheter, may be necessary. Intravenous access through several large-bore catheters is also critical. Intravenous fluids and blood products should be administered through a fluid warmer to prevent hypothermia. A rapid fluid infuser is commonly used. Cell-scavenging techniques are useful to reduce the requirement for donor packed red blood cells. Placement of an epidural catheter for postoperative pain control can be considered, provided that the patient is not coagulopathic and after the neurovascular integrity of the lower extremities has been confirmed. Patients may be admitted to the ICU postoperatively for monitoring, and are sometimes intubated, especially in the presence of evolving pulmonary injuries (fat embolism, aspiration, or lung contusion), or other complicating organ injuries.

Femur Fractures

Fractures of the proximal femur following mechanical falls are most common in elderly patients and are associated with high morbidity and mortality (1-year mortality of up to 30%).[164] In younger patients, femur fractures including fractures of the femoral shaft and distal femur are usually associated with trauma, such as following motorcycle and motor vehicle accidents. Perioperative complications are often related to preexisting cardiac and pulmonary conditions and include myocardial infarction and dysrhythmias, DVT, pulmonary embolism, and delirium. It has been shown that older patients admitted early into a dedicated orthogeriatric facility have a improved long-term mortality.[165]

Proximal femur fractures occur through the femoral neck, intertrochanteric, or subtrochanteric areas. Displaced femoral neck fractures are usually treated by prosthetic replacement, whereas intertrochanteric or subtrochanteric fractures can be treated with a sliding hip screw and side plate, cephalomedullary nail, or blade plate. Nondisplaced femoral neck fractures are usually managed by closed reduction and percutaneous pinning.[166] Surgical treatment of femoral shaft and distal femur fractures involves application of plates and screws along the femur for rigid internal fixation and intramedullary devices.

Pain and stress following hip fracture can often contribute to myocardial ischemia. Therefore, a thorough preoperative evaluation and preparation of these patients, as outlined earlier in this chapter, is crucial. Early surgery (<24 hours) has been associated with reduced pain and length of hospital stay but not improved function or mortality.[167] However, patients with significant medical comorbidities that delay surgery for more than 4 days have a nearly 2.5 times higher risk of death within 30 days after the surgery compared with patients who are initially considered fit for surgery.[164] Thus, early surgery for hip fractures combined with early mobilization and rehabilitation should be the goals for medically stable patients.

Given the existing evidence that regional anesthesia can be associated with lower morbidity (including reduced risk of DVT, pulmonary embolism and respiratory complications, and a decrease in intraoperative blood loss) and mortality,[168] it is reasonable to consider regional anesthesia in patients with hip fractures.[169] A carefully dosed spinal anesthetic with isobaric bupivacaine often provides stable anesthesia of sufficient duration for the surgical repair. Anesthesia from T12 to S2 is adequate. Use of anticoagulation for prevention of DVT and pulmonary embolism may limit the use of postoperative epidural analgesia. There is evidence that regional nerve blocks including fascia iliaca blocks can effectively reduce pain associated with hip fracture. There is also moderate evidence that nerve blocks may contribute to reduced rates of delirium, and potentially, reduced length of inpatient stay, morbidity, and mortality.[170]

Pulmonary embolization of bone marrow debris and bone cement leading to hypoxemia and right ventricle failure is a major determinant of mortality in these patients.[171] The presence of emboli detected by intraoperative TEE in the right heart and pulmonary artery appears to derive principally from the reaming of the femoral canal and the placement of the femoral stem, particularly during the placement of cemented prostheses (see earlier).[159] Although routine use of intraoperative TEE is not recommended, it may be considered in high-risk patients with femur fractures. Adequate intravenous access and cross-matched blood products should be available, because some of these procedures can involve a large blood loss. Placement of an arterial catheter allows timely and accurate blood pressure monitoring, and serial measurements of arterial blood gases and hemoglobin concentrations. The use of a central venous catheter may also be indicated in high-risk patients. Maintaining body temperature during surgery is particularly important in the older patient population. Medically unstable patients with significant comorbidities often require postoperative management in an ICU setting.

Tibia Fractures

Tibial plateau or proximal tibia fractures are most common in younger trauma patients, as well as elderly patients with degenerative arthritis of the knee. Open reduction internal fixation of tibial plateau fractures involves a reduction under direct visualization of the fracture fragments and application of plates and screws along the tibia for rigid internal fixation. An iliac crest bone graft may also be necessary. Compartment syndrome is one of the most frequent complications of this surgery (10%-20%). Tibial shaft fractures are commonly associated with trauma (95%) and are treated by intramedullary nailing of the tibia. Most nails are interlocked proximally and distally with screws. External fixation of tibia fractures involves placement of percutaneous pins that are clamped to an external frame. This procedure can be used for temporary stabilization of tibia fractures, especially in the setting of periarticular injuries. These fixators also may be useful for salvage of open and/or infected fractures that are unsuitable for internal fixation.[172] Tibia surgeries are frequently performed under general anesthesia, although spinal anesthesia could also be considered. Regional blocks can also be considered for postoperative pain control if compartment syndrome is not a major concern. In fact, evidence suggests that in most patients, regional techniques do not interfere with diagnosis of compartment syndrome.[173]

Upper Extremity Fractures

Trauma patients presenting for surgeries for upper extremity fractures are relatively young and often otherwise healthy. Most of these surgeries are performed on an elective basis with a standard preoperative evaluation. However, repairs of compound fractures and open fractures may necessitate emergency surgery. General or regional anesthesia or their combination can be used. A brachial plexus block via the supraclavicular, infraclavicular, or axillary approach is suitable for surgeries of the distal arm, whereas the interscalene approach is employed for more proximal humerus procedures. A peripheral nerve catheter may be considered for postoperative pain relief. Regional techniques can be safely applied when there is no concern for postoperative compartment syndrome.

Extremity Replantation

Functional recovery remains the overarching goal of extremity replantation. Traumatic amputation disproportionately affects males in a 4:1 ratio. Most upper extremity amputations occur at the level of the digits. Life-threatening injuries, if present, must be prioritized before consideration is given to replantation. The ultimate surgical plan is often deferred until after microscopic examination of the stump and amputated parts. Severe crush or burn injuries massive contamination, multiple injuries in the same digit, prolonged normothermic ischemia, and preservation of amputated parts in nonphysiologic solutions are relative contraindications to proceeding with replantation.

To minimize irreversible tissue injury, hypothermic preservation of the amputated part and measures to reduce the interval between amputation and replantation are routinely practiced. The goal for successful digit replantation is to be completed within 12 hours of warm or 24 hours of cold ischemia. The window is narrower for major upper extremity implantation (6 hours of warm and 12 hours of cold ischemia).[174] Extremity replantation is hence an emergent procedure and patients often present having full stomachs. Substance abuse is common in this population and acute intoxication may raise additional concerns, such as altered anesthetic requirement, diuresis, and hypovolemia or hypothermia. The patient may also present with acute blood loss anemia depending on the extent of the traumatic injury. Regional anesthesia is typically used either alone or in conjunction with general anesthesia to provide postoperative analgesia and most importantly, vasodilation to the vascular anastomosis. Indeed, brachial plexus nerve catheters have been shown to improve the blood flow to the implant through vasodilation.[174-176] As a surrogate marker of tissue perfusion, skin temperature is elevated in patients having brachial plexus blocks.[177] Furthermore, one study demonstrated a 0% reoperation rate for vascular insufficiency in patients having continuous supraclavicular blocks, versus 29% reoperation rate in patients managed with intravenous opioids alone.[178] The surgical team often performs the replantation in the following sequence: bone fixation, tendon repair, nerve repair, vascular anastomosis, and skin closure. Typical donor sites for skin grafts include stomach and thigh. Intravenous heparin and dextran are typically administered during the microvascular portion of the surgery to minimize the risk of thrombosis, which complicates 10% of cases. In theory, vasopressors should be avoided; however, there is little evidence to support this claim clinically. A tourniquet is routinely used to minimize blood loss, but a baseline complete blood count and a blood bank sample are prudent in the setting of any traumatic injury. Reperfusion intervals for tourniquet times of greater than 90 to 120 minutes should be considered. Lactic acidosis from a prolonged tourniquet time may be problematic in patients with underlying lung disease, and maintaining controlled ventilation is advisable in such patients in order to compensate the metabolic acidosis.

Surgical duration is variable. The clinician should meticulously position and monitor all pressure points, given probable length of procedure. Techniques to maintain perioperative normothermia, such as fluid warmers and heating blankets, are employed to prevent vasospasm. After the procedure, it can be helpful to admit the patient into a room with increased ambient temperature to promote vasodilation. In addition, anticoagulant therapy may need to be continued to prevent microthrombi. The peripheral catheters should be monitored regularly by a dedicated team and coagulation status should be checked prior to discontinuing the catheter. Patient controlled analgesia (PCA) is a useful alternative in the initial days following the procedure, but opioid utilization can be reduced by peripheral nerve block or catheter.

UPPER EXTREMITY SURGERIES

Hand Surgery

Hand surgeries are performed by several surgical specialties including general surgeons and orthopedic surgeons, as well as plastic and hand surgeons. These cases vary in complexity from a simple incision and drainage to complete neurovascular replantation of several digits and even the entire hand, as well as urgency from elective surgeries to emergent procedures such as replantation of ischemic digits. Hand procedures can vary widely in length from several minutes to several hours. Less complex procedures are performed at outpatient surgical centers, whereas complex procedures are reserved for tertiary care hospitals. Given the varying nature of hand surgeries, the anesthetic approaches to hand cases also vary from intravenous anesthesia or Bier block to regional anesthesia or general endotracheal anesthesia.

Intravenous regional anesthesia (or Bier block) is a simple technique that involves exsanguinating the arm by wrapping it with an elastic bandage (e.g., Esmarch bandage), inflating an upper arm tourniquet to between 50 and 100 mm Hg above the patient's systolic blood pressure (often to 250 mm Hg), and injecting a short-acting preservative-free local anesthetic (typically lidocaine) into a hand vein. A second tourniquet, distal to the first, may be inflated 15 minutes later with subsequent deflation of the first, to minimize tourniquet pain. The extremity veins distal to the tourniquet are filled with the anesthetic agent, which sets in after approximately 6 to 8 minutes. Complications occur when the tourniquet fails during initial anesthetic injection or if the tourniquet is deflated too early (<30 minutes), risking systemic local anesthesia toxicity. Adjuncts can be added to the local anesthetic injectate including ketorolac and clonidine to extend duration of analgesia, but their routine use is discouraged by most experts, because the potential benefits do not seem to outweigh the risk of increased complexity and side effects.

Regional anesthesia techniques for hand surgery include blocking the brachial plexus via an infraclavicular (ICB) or axillary approach. Two large series of infraclavicular blocks reported 90% to 94% success with only posterior cord stimulation using a nerve stimulator; other reports recommend a double stimulation technique for a better success rate. Ultrasound-guided ICB continues to gain popularity, as its first pass success is superior to the nerve stimulator technique. As with the nerve stimulator technique, injecting local anesthetic at the posterior cord increases the success rate.[179] Moreover, performing ICB with ultrasound guidance may shorten procedure time, avoid the need for multiple needle passes, and reduce complications of vascular puncture and pneumothorax.[180] For high-risk patients who are anticoagulated, an axillary block is a reasonable option, as the artery is easily compressible. With ultrasound guidance, selective nerve blockade can be achieved to minimize bleeding potential. For complex and emergent hand cases, general anesthesia is often chosen because of the prolonged duration of the procedure (see trauma section earlier).

Shoulder and Elbow Surgery

Over the past several decades, an increasing number of patients have undergone shoulder surgeries, as it has been shown that these procedures have a positive impact on the quality of life. Shoulder arthroplasty surgery can range from extensive open repairs, hours in duration, to simple shoulder arthroscopic procedures of short duration. Most of the surgeries are performed in the beach chair position, as this position offers superior surgical exposure and access, less distortion of muscle anatomy, and less tension on the brachial plexus than the lateral position. Therefore, anesthetic considerations are mostly tailored to counterbalance the physiologic derangements occurring in this position in anesthetized patients. Anesthetic techniques can range from general anesthesia to conscious sedation or monitored anesthesia care with regional block. For the most part, open procedures require muscle relaxation and therefore, general endotracheal anesthesia is often preferred. For arthroscopic procedures, muscle relaxation is not necessary, and these cases can be amenable for general anesthesia with a LMA or monitored anesthesia care with regional block. The anesthetic approach is largely influenced by the local practice culture. Surgeons may request controlled hypotension in arthroscopic cases, as visualization can be hindered by local bleeding. This can be problematic, especially in patients with chronic uncontrolled hypertension, as well as those with underlying cerebral vascular insufficiency. Cerebral perfusion pressure (CPP) is reported to decrease by 15% in sitting patients under general anesthesia. In patients with chronic hypertension, cerebral autoregulation is altered, and the curve is shifted to the right (Fig. 64.10). In patients with cerebrovascular disease, detrimental decrease in cerebral blood flow (CBF) can occur if the systemic pressure is kept below the minimal required CPP. Cerebral autoregulation is also influenced by ventilation via arterial PCO_2. Hypercapnia can result in cerebral vasodilation and increased CBF at a constant CPP. Conversely, hypocapnia causes a decrease in CBF due to cerebral vasoconstriction.[181] A randomized study suggested that cerebral oxygenation can indeed be improved with higher end tidal CO_2 during surgery in the beach chair position.[182] Therefore, permissive hypercapnia may be considered during shoulder surgery in the sitting position for patients with altered CBF. Additionally, the effects of vasopressors, such as phenylephrine, in the sitting position should be taken into account, as high doses of vasoconstrictors can affect CBF. In a study measuring cerebral oxygen saturation in the sitting position, desaturation occurred with the use of phenylephrine. The study concluded that cerebral oxygenation can be used to provide an endpoint for vasopressor therapy.[183] Another important anesthetic factor to consider when allowing hypotension in the beach chair is the distance discrepancy between the measurement of noninvasive blood pressure (NIBP) and the circle of Willis. In the supine position, the height of the NIBP at the arm and the circle of Willis are about the same. Therefore, the blood pressure reading closely approximates the CPP. However, in the sitting position, the blood pressure reading from the arm is different than the actual CPP at the circle of Willis. In general, for every 10 cm rise of an organ or tissue, there is 7.5 mm Hg drop in its mean arterial pressure. In the sitting position, the distance between the blood pressure cuff at the arm and Circle of Willis can approximate 20 cm. A technique to mitigate the distance is to decrease the angle of the sitting position. When inducing hypotension in the sitting position, all these factors have to be taken into account and discussed in a preoperative huddle with the surgeon. It is important to note that the role of the sitting position (beach chair) on postoperative neurological outcome remains controversial. According to the Anesthesia Patient Safety Foundation Beach Chair Study, there were no differences in postoperative cognition or brain injury biomarkers when compared to the supine position.[184]

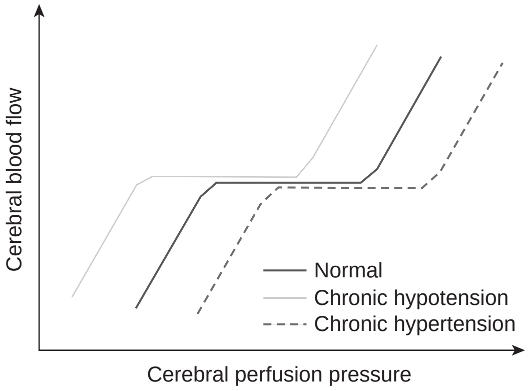

Fig. 64.10 Cerebral autoregulation curve.

Another serious complication that has been reported during shoulder surgery is excessive hypotensive and bradycardic events, some progressing to asystolic arrest, under monitored anesthesia care with regional anesthesia. There is some evidence that these events are the result of a cardiac inhibitory reflex, or the Bezold-Jarisch reflex, which occurs in response to diminished ventricular volume (venous pooling in the sitting position) in a hypercontractile ventricle. Prophylactic administration of β-blockers and intravenous fluids may reduce the incidence of these events.

Regional anesthesia, specifically interscalene block (ISB), continues to gain popularity for shoulder surgeries, as it can provide postoperative analgesia and decrease opioid consumption. For shoulder arthroscopies, single -shot ISB has been associated with less time spent in the postanesthesia care unit, better patient satisfaction, and fewer complications.[185] ISB can be utilized as the sole anesthetic for shoulder surgeries. However, this approach is not widely practiced.[186] One must be mindful of the impact ISB can have on pulmonary function secondary to ipsilateral phrenic nerve weakness. If prolonged analgesia is desired (>24 hours), placement of an interscalene catheter can be considered. Patients can be discharged with an infusion pump and can even self-discontinue the catheter at home.[187] Alternatives to ISB include selective suprascapular nerve (SSN) block, intraarticular analgesia, and oral analgesia. SSN block is performed with the patient sitting, and local anesthesia is injected at the suprascapular fossa, avoiding the vessels that travel with the nerve. This technique partially covers the shoulder but has no cutaneous coverage.[188] Ultrasound guidance can be used to block the nerve at the suprascapular fossa or at the suprascapular notch. An anterior ultrasound approach can be employed to trace the SSN from the interscalene groove at C5 down to below the omohyoid muscle. Injection at this site has been shown to result in less motor blockade than ISB and equivalent analgesia.[189] Intraarticular anesthesia is another alternative approach to postoperative pain control after shoulder surgery and involves injecting local anesthetic agents. This technique has been shown to significantly reduce post-surgical opioid consumption.[190] Recently, a long-acting formulation of bupivacaine, liposomal bupivacaine, was tested for perioperative peripheral nerve blockade. A small randomized prospective study compared locally infiltrated liposomal bupivacaine versus conventional ISB and found increased pain in the immediate postoperative period in patients receiving liposomal bupivacaine. However, opioid consumption was greater in the ISB group 13 to 16 hours after surgery. Beyond 24 hours, there was no difference in the two groups in terms of their pain scores, hospital length of stay, or number of complications. This study concluded that overall liposomal bupivacaine offered comparable analgesia to ISB, but could help reduce overall opioid consumption.[191] Larger studies are being conducted to further investigate the role of liposomal bupivacaine in shoulder surgery.

In contrast to shoulder surgery, elbow surgery does not require beach chair position, and the patient is usually in supine or lateral decubitus position. Common elbow surgeries include fixation of fractures as well as neurovascular repair. Most surgeries are performed under general anesthesia; however, monitored anesthesia care with regional block can be considered for selected patients and procedures and when there are no concerns for irreversible nerve injuries or compartment syndrome.

As with shoulder and hand surgeries, regional anesthesia can play a major role in postoperative analgesia after elbow surgery. The infraclavicular approach (ICB) to blocking the brachial plexus is common, but data suggest that a supraclavicular block may be just as effective.[192] Supraclavicular block spares the intercostobrachial nerve providing cutaneous innervation of the medial upper arm at the T2 dermatome. If a tourniquet is used, blocking the T2 can help decrease tourniquet pain.

LOWER EXTREMITY SURGERY

Knee and Hip Arthroscopy

Arthroscopic procedures for the knee, hip, and ankle are increasingly performed as ambulatory procedures. These cases can be challenging for the anesthesiologist who must decide on the appropriateness of the patient and procedure for outpatient surgery and an anesthetic that is adequate for the procedure, but also satisfy the patient's expectation of an uncomplicated postoperative recovery with minimal pain.

General anesthesia is safe and effective for arthroscopic surgery, but it has been associated with increased postoperative nausea and vomiting and pain. In a prospective study of 1088 patients for ambulatory surgery, Pavlin and coworkers reported that the most important factors in determining the time to discharge were pain, unresolved neuraxial blocks, nausea and vomiting, and urinary retention.[193] This study emphasizes the role of anesthesia in prolonging ambulatory surgical stay. A properly designed regional anesthetic approach may reduce the impact of some of these factors.

Arthroscopic knee surgery can be performed with a combination of extraarticular and intraarticular injections of local anesthetics. Short-duration local anesthetics may be combined with longer-acting local anesthetics (bupivacaine) and morphine to provide postoperative analgesia. Intraarticular morphine has not been shown to provide significant additional analgesia after arthroscopic knee surgery. For more involved arthroscopic procedures, such as an anterior cruciate ligament repair, surgical relaxation may be required. Spinal anesthesia provides excellent operating conditions for these procedures. Problems related to neuraxial anesthesia for ambulatory surgery include unpredictable onset and regression of the blockade, urinary retention, and transient neurologic symptoms (TNS). A dose of 45 mg of isobaric spinal mepivacaine has been reported to result in a mean motor block of 142 ± 37 minutes. Using 30 to 40 mg of spinal chloroprocaine, Yoos[194] reported 155 ± 34 minutes to ambulation in outpatient surgical patients. TNS include pain in the gluteal region that can radiate down both legs and appear within a few hours to 24 hours after an uneventful spinal anesthetic. The incidence of TNS is more frequent after outpatient surgery performed in the lithotomy position and in patients undergoing knee arthroscopy. The pain can vary from mild to severe and last 2 to 5 days. It is best treated with NSAIDs. TNS is more common after a spinal anesthetic with lidocaine (~14%) than with mepivacaine (6.5%) and bupivacaine (<1%). For ambulatory patients, the benefit of short-acting spinal anesthetic must be weighed against the risk for developing TNS. For postoperative analgesia after anterior cruciate ligament repairs, a femoral nerve block (FNB) with a long-acting local anesthetic is superior to intraarticular injections. Because the quadriceps muscle is blocked, however, it is important for the patient to be fitted with a knee brace before ambulation. Blocking the femoral nerve at the adductor canal (adductor canal block [ACB]) can also provide postoperative analgesia without interfering with early ambulation, as quadriceps strength is preserved when compared to FNB.[195] However, the analgesia does not cover the posterior aspect of the knee.

Hip arthroscopy has become a common outpatient procedure for the diagnosis and treatment of pathologic processes in the hip. The patient can be placed in either the supine or the lateral position (operative side up) with 50 to 75 lbs (22-34 kg) of traction applied to the operative limb to gain access to the joint with the arthroscope. In positioning the patient, the anesthesiologist must ensure that the perineal post is padded and not compressing the pudendal nerve and that excessive traction for prolonged periods is not applied. Because complete muscle relaxation is usually required for the procedure, the patient must have either a general anesthetic or a neuraxial block. A lumbar plexus block can be performed for postoperative analgesia.

Hip and Knee Arthroplasties

As was described earlier in this chapter, hip and knee joint replacement are among the most common surgeries in the United States. THA may be performed via an anterior or lateral approach. The anterior approach offers the advantage of exposure without violation of the muscles, but restricts full access to the femur, with the risk for lateral femoral cutaneous nerve injury. The lateral posterior approach provides excellent exposure to the femur and the acetabulum with minimal muscle damage but increases the risk for posterior dislocation. Most surgeons prefer the lateral posterior approach, which places the patient in the lateral decubitus position, surgical side up, for the operation. The anesthesiologist must be aware that this position may compromise oxygenation, particularly in obese and severely arthritic patients, as a result of ventilation-perfusion mismatch.

In addition, to prevent excessive pressure on the axillary artery and brachial plexus by the dependent shoulder, a soft roll or pad may be placed beneath the upper thorax.

The nerve supply to the hip joint includes the obturator, inferior gluteal, and superior gluteal nerves. Regional anesthesia for THA can be achieved with a spinal or epidural anesthetic. Although most studies suggest decreased postoperative respiratory complications, including venous thrombosis and pulmonary embolism with regional versus general anesthesia, some controversy still remains. It is, nevertheless, important to note that regional anesthesia has been associated with a reduction in deep surgical site infection rates and hospital length of stay.[196]

Blood loss during THA can be significant, particularly for revision surgeries. Controlled hypotensive anesthesia may reduce intraoperative blood loss. The administration of TXA has also been shown to reduce blood loss during joint arthroplasty (see earlier). The femoral vein can be obstructed during dislocation of the hip and reaming and insertion of the femoral prosthesis, which can result in blood stasis and clot formation. With relocation of the hip and unkinking of the femoral vein, the embolic material can be released into the circulation. An unfractionated heparin bolus before the femoral work has been suggested to reduce the strong thrombotic stimulus and should be considered in selected patients.

Similar to THA, anesthetic options for TKA include general or neuraxial anesthesia. A less common approach is the combination of a femoral and sciatic block, but in patients with valgus deformities, this approach may prevent the early detection of sciatic and peroneal nerve palsies. A 2016 systematic review of the literature found that neuraxial anesthesia is as effective as general anesthesia without increased morbidity, and that limited quantitative evidence supports the notion that perioperative outcomes are improved with neuraxial anesthesia.[197] Another benefit of regional anesthesia is decreased postprocedural opioid consumption.

Patients who have undergone TKA have severe postoperative pain, and several studies have reported a reduction in postoperative complications and improved outcomes when this pain is managed with regional anesthesia. Single-injection FNBs in combination with intravenous and epidural PCA have been employed to manage postoperative pain and improve functional recovery. Infusion of local anesthetics through continuous femoral nerve catheters may also be used in place of patient-controlled epidural analgesia. Both FNB and epidural anesthesia have been associated with delayed ambulation post TKA. There have been recent efforts to fast track recovery for arthroplasty patients and aim for early mobility via early physical therapy. This has been shown to improve long-term functional status. As a result, there has been a shift away from FNBs and epidural anesthesia in favor of ACBs. A large meta-analysis suggested that patients who received ACB combined with periarticular local anesthesia injection could ambulate sooner than those with periarticular injection alone. No differences in postoperative analgesia or opioid consumption were noted.[198] Intraarticular multimodal injection of ropivacaine, ketorolac, clonidine, and epinephrine in combination with oral acetaminophen, celecoxib, and oxycodone was, nevertheless, shown to decrease opioid-analgesic requirements and increase patient satisfaction after TKA.[199-201]

A pneumatic tourniquet is routinely inflated over the thigh during TKA to reduce intraoperative blood loss and provide a bloodless field for cement fixation of the femoral and tibial components. Bleeding begins with the deflation of the tourniquet and can continue for the next 24 hours. Tourniquets are usually inflated to a pressure 50 to 100 mm Hg above the patient's systolic blood pressure for a maximum of 3 hours. Nerve injury after tourniquet inflation has been attributed to the combined effects of ischemia and mechanical trauma. When prolonged tourniquet inflations are required, deflating the tourniquet for 30 minutes of reperfusion may reduce neural ischemia.

Pain related to tourniquet inflation also may occur after 60 minutes, despite the presence of a regional anesthetic that is adequate for the surgery. It has been postulated that tourniquet pain is caused by the unblocking of unmyelinated C fibers during recession of a neuraxial block. The addition of opioids to spinal or epidural anesthesia may ameliorate tourniquet pain. After tourniquet release, mean arterial blood pressure decreases significantly, partly owing to the release of metabolites from the ischemic limb into the circulation and the decrease in peripheral vascular resistance. In patients with known preexisting sciatic neurapraxias, neuropathic pain, and vascular disease in the operative leg, the operation can be performed without a tourniquet.

Many patients have symptomatic arthritis of both knees and require bilateral TKA to achieve functional improvement in pain and lifestyle. However, controversy still exists as to whether both knees should be replaced sequentially in a single operation (simultaneous bilateral total knee arthroplasty [SBTKA]) or through a two-stage procedure. The advantages of SBTKA include exposure to the risks of one anesthetic course one postoperative course of pain, reduced rehabilitation and hospitalization, and an earlier return to baseline function. However, SBTKA has been associated with a higher incidence of serious perioperative complications such as myocardial infarction, fat embolization, and thromboembolic events.

Foot and Ankle Surgery

Similar to most hand surgeries, foot and ankle surgeries are classified as low-risk procedures. However, the low-risk nature of the procedures can pose a challenge for clinicians when caring for high-risk patients. The risks and benefits must be carefully considered when crafting an anesthetic plan, which can include general endotracheal anesthesia, general anesthesia with a LMA, neuraxial anesthesia with spinal or epidural, and regional anesthesia. Muscle relaxation is often not required. In caring for patients undergoing these procedures, length of procedure, patient position, and institutional preferences are considered when deciding on anesthetic approach and patient monitoring. Unlike hand cases, patient positioning can vary from supine, to lateral decubitus, to prone positioning. Most elective cases are done as outpatient surgery. Trauma cases can be long in duration, especially with complex fractures of the distal tibia. Infected toe and foot surgeries can be performed quickly, but patients may present with sepsis due to gangrenous tissue. It is not unusual to find that the patient who requires foot and ankle surgery is immunocompromised, diabetic, or has vascular insufficiency. Bleeding can occur, but generally it is not a main concern. Thigh or leg tourniquets are often used to limit blood loss.

Surgery of the foot and ankle is associated with high postoperative pain. Regional anesthesia can be beneficial and is commonly used as the primary anesthetic or for postoperative analgesia. These cases are ideal for regional anesthesia also because many patients are instructed to avoid bearing weight after surgery, and hence motor weakness is not a concern. Regional anesthesia that combines sciatic and FNBs is sufficient for all surgical proceures below the knee that do not require a thigh tourniquet. The femoral nerve innervates the medial leg to the medial malleolus, and the remainder of the leg below the knee, including the foot, is innervated by sciatic nerve via the common peroneal nerve and tibial nerve. The sciatic nerve is usually blocked high in the popliteal fossa to ensure anesthesia to the tibial and peroneal nerves. The nerve can be identified via a nerve-stimulating needle with foot inversion as the motor response. Increasingly, however, the sciatic block is performed with ultrasound guidance. For procedures that also involve the medial aspect of the leg, the femoral nerve can be blocked, commonly at the adductor canal, at the level of the knee via the medial femoral condyle, below the knee with local infiltration distal to the medial condyle of the tibia, or above the medial malleolus of foot. Each of these approaches has various degrees of success, with the highest success being the ACB.[202] The popliteal sciatic nerve block has been shown to reduce postoperative pain and opioid requirements after foot and ankle surgery when performed as a single preoperative injection or as a continuous catheter infusion. Studies suggest that for ultrasound-guided sciatic blocks, optimal onset and analgesia is achieved when the local anesthetic is injected distal to the sciatic bifurcation.[203,204] For sciatic catheters, optimal analgesia is achieved when the catheter is placed 5 cm proximal to the sciatic bifurcation.[205] Liposomal bupivacaine is being investigated as an alternative to regional anesthesia for local infiltration.[206]

A discussion with the surgeon about the risk for compartment syndrome should occur before administering long-acting sciatic nerve blocks. However, there is increasing evidence that regional anesthesia may not mask ischemic pain from compartment syndrome, and this question remains controversial.[173,207] Ankle block can be used for surgical procedures on the foot that do not require the use of a thigh or calf tourniquet, although an ankle-level Esmarch tourniquet may be used. It is commonly used for toe amputations and is also a highly effective technique for bunion surgery.[208]

Five terminal nerves are usually blocked to provide complete anesthesia to the foot: (1) posterior tibial nerve, which provides sensation to the plantar surface; (2) saphenous nerve, which innervates the medial malleolus; (3) deep peroneal nerve, which supplies the interspace between the great and second toes; (4) superficial saphenous nerve, which supplies the dorsum of the foot and the second through the fifth toes; and (5) sural nerve, which supplies the lateral foot and lateral fifth toe (Fig. 64.11). Mineo and Sharrock reported that ankle block performed at the midtarsal level with 30 mL of 0.75% bupivacaine provided a mean duration of 17 hours of analgesia with safe blood levels of local anesthetic.[209]

Anesthesia for Spine Surgery

With the wide spectrum of spine disorders and an expanding array of treatment options, spinal surgeries have become increasingly prevalent over time. According to the Healthcare Cost and Utilization Project, spinal fusions and laminectomies were among the most common operations during inpatient stays in 2015, with an estimated rate of 147 and 136 per 100,000, respectively. In absolute numbers, it was estimated that an excess of 500,000 spinal fusions were performed in community hospitals alone in the United States.[210] Although only less than 10% of these surgeries are currently performed in an ambulatory setting, it is expected that with technical advances and enhanced perioperative care, an increasing number of these patients will qualify for outpatient surgery. Moreover, a growing number of patients with major comorbidities are being considered for complex spine surgeries such as scoliosis correction or spinal stabilization after trauma or neoplastic diseases. The underlying cardiovascular, respiratory, or neurologic disorders in combination with the physiologic stress from a large spinal procedure places the patient at a higher risk for perioperative complications. As described earlier in this chapter, preoperative optimization of the underlying diseases and careful perioperative care that involves the surgical, anesthesia, rehabilitation, and other medical teams can minimize the risk for these complications and improve the overall outcome.

PREOPERATIVE ASSESSMENT

The preoperative assessment for spinal surgeries should include a comprehensive evaluation of the neurologic function and possible symptoms or deficits associated with the underlying spinal disorder. The potential for difficulty in airway management should always be considered in patients with cervical and thoracic spine disease. Stability of the cervical spine and its range of motion should be assessed and documented, and the anatomic and functional relationship between the airway and the cervical column carefully considered. Video laryngoscopy or fiberoptic intubation may be needed and if awake intubation is considered, it is important to assess the patient's ability to cooperate. A multidisciplinary preoperative conference to review the suitability of each patient and discuss the medical, surgical, anesthesia, and rehabilitation implications of the procedure can improve the quality and safety in complex spine surgery.[211] In addition to a comprehensive review of the patient's preoperative cardiovascular, pulmonary, and neurologic comorbidities, basic hematologic, hepatic, and renal values, their preoperative optimization, perioperative pain control, and rehabilitation potentials also need to be considered.

SPINAL TRAUMA

Trauma victims with spinal cord injury (SCI) represent a group of patients with unique perioperative challenges. The incidence of nonfatal SCI is estimated to be 40 per 1 million population in the United States, or approximately 12,000 new cases each year.[212] Most injuries occur between the ages of 16 and 30. One retrospective analysis examined more than 500 patients with traumatic spinal fractures and found that 39% were caused by a high-energy fall and 26.5% by motor vehicle accidents.[213] The high-energy fall etiology resulted in injuries distributed throughout the spine, whereas motor vehicle accidents most frequently impacted the cervical and thoracic spine. Twenty-five percent of patients with spinal fracture had motor and/or sensory deficits, and the highest number of patients with complete motor and sensory neurologic deficits had sustained cervical fractures. Types of fractures were distributed as follows: compression fractures in 54.8% of patients, distraction fractures in 16.9%, and rotational fractures in 18.5%. Compression fractures occur when the vertebral body cannot handle a sudden force and fractures. This commonly occurs in the setting of osteoporosis and malignancy. A wedge fracture is a subtype, which often involves the anterior collapse of the vertebral body. Burst fractures occur as a result of severe trauma, such as a motor vehicle accident. Vertebrae are crushed by an extreme force and are impacted in multiple places. Flexion-distraction fractures typically involve the middle and posterior column of the spinal column. Flexion-dislocation fractures can include any of the aforementioned fracture types and occur when the vertebrae move significantly. Anterior, middle, and posterior columns are usually involved. This is an unstable fracture. With most SCIs caused by falls or motor vehicle collisions, it is not unusual that these patients also suffer injuries to the face and airway or present with traumatic brain injury, rib fractures and lung contusions, extremity or pelvic fractures, vascular injuries, or hepatic or splenic lacerations. The initial SCI may be caused by mechanical force from bony fragments from the vertebral body, facet or intervertebral joint dislocation, ligamentous tears or herniation of intervertebral discs, or arthropathies such as spondylosis or spondylolisthesis. Following the initial injury, systemic inflammation, ischemia or hypoxia, and excitotoxicity or lipid peroxidation and apoptosis of neurons can result in progression of the neurologic symptoms and worsening outcome. If facial or cervical spine injuries are present, airway management can be particularly challenging. Unstable cervical spine injury constitutes approximately 14% of SCI cases.[214] Techniques to minimize cervical movement should then be employed during management of the airway. Because of the urgent nature of airway interventions, many practitioners continue to use direct or indirect laryngoscopy with manual in-line stabilization (MILS), which applies opposite forces to the head and neck to limit the movement. The incidence of intubation-related neurologic impairment has been reported to be very low when MILS is applied during endotracheal intubation in patients with SCI.[215] However, MILS can worsen laryngeal visualization during direct laryngoscopy and increase the rate of tracheal intubation failure.[216] Rigid indirect video laryngoscopy is a reasonable alternative to conventional direct laryngoscopy and in skilled hands can minimize cervical motion during intubation, although studies have failed to confirm any clear advantages.[217] Obviously, fiberoptic intubation is often the safest approach in patients with cervical spine instability, but clinicians must also consider the patient's ability to cooperate during an awake fiberoptic intubation, as well as the risk of aspiration if deep sedation or general anesthesia is required. Neuromuscular blockade may be needed to facilitate intubation, but it is important to consider the risk of induced hyperkalemia associated with depolarizing neuromuscular blocking agents in these patients. Succinylcholine should be avoided after the initial 48 to 72 hours following an SCI.[218,219]

Another important challenge in patients with SCI is systemic hypotension, which can be caused by hemorrhage from associated injuries. In addition to hypovolemia, a common cause of hypotension in patients with high cervical SCI is neurogenic or spinal shock, which is characterized by bradycardia as well as vasodilation associated with the loss of central supraspinal sympathetic control.[220] If not appropriately managed, hypotension after SCI can compromise spinal cord perfusion and lead to secondary cord injury. The American Association of Neurological Surgeons (AANS) has, therefore, recommended that systemic arterial pressure be maintained at greater than 90 mm Hg for 5 to 7 days after SCI (class 3 evidence).[221] Although it remains controversial, data from a Cochrane review support a 48-hour course of high-dose steroids initiated within 8 hours of injury to those patients with incomplete neurologic deficits.[222]

COMMON SPINAL PROCEDURES

According to the Nationwide Inpatient Sample and the National Hospital Discharge Survey, discectomies, spinal decompression, instrumentation, and fusion are the most frequently performed spinal procedures in the United States. Anterior cervical discectomy is indicated in patients with spinal cord or nerve root compression from herniated disks or osteophytes. Patients often present with radiculopathy, myelopathy or, if they also suffer ligamentous laxity or disruption, cervical instability. A left-sided approach is usually preferred, as it minimizes the risk of recurrent laryngeal nerve injury. The disk is excised in a piecemeal fashion and bone graft placed in the intervertebral space with fusion performed to maintain stability, the disk height, and normal cervical lordosis. Posterior foraminotomy has the advantage that it does not require fusion and hence preserves the motion, but it is not effective for midline disk herniation and is more often associated with postoperative pain. Cervical canal stenosis or tumors may require decompressive laminectomy through a posterior approach. Obviously, the dura will need to be opened for resection of intradural masses, and it is then reasonable to avoid excessive reverse Trendelenburg, as it can increase the risk for pneumocephalus.[223] After the dura is closed, its integrity can be tested with a Valsalva maneuver.

Lumbar laminotomy and laminectomy are commonly employed for decompressing the neural elements of the lumbar spine. Posterior lumbar fusion is used for treatment of low-back pain associated with segmental or iatrogenic lumbar instability and spondylolisthesis and is commonly approached through a posterolateral fusion (PLF) or posterior lumbar interbody fusion (PLIF). PLF combines decompressive laminectomy and discectomy with PLF through decortication and bone grafting of the facet joints and transverse processes, whereas in PLIF the bone graft is packed into the disk space between the vertebral bodies after total discectomy and removal of the cartilaginous end plates. In both approaches, fusion is facilitated, and stability obtained through insertion of pedicle screws and a rod construct. Pedicle screw stabilization remains the preferred mode of instrumentation and provides rigid three-column fixation, but screw malposition can cause nerve-root injury. There are no major differences in clinical outcome or complication rates, but PLIF has been associated with better fusion rates and pain scores in the treatment of lumbar spondylolisthesis.[224] Minimally invasive surgery (MIS) techniques are increasingly employed and include direct or extreme lateral interbody fusion (DLIF or XLIF), where the spine is approached laterally through the retroperitoneal cavity, and transaxial lumbosacral fusion (Transl) through a 1 cm incision at the base of the sacrum. Blood loss is minimal with MIS, but occult injury to peritoneal contents have been reported.

Scoliosis can be classified as congenital, neuromuscular, or idiopathic. With an incidence of 4 per 1000, idiopathic scoliosis accounts for the majority (about 80%) of cases. A Cobb angle of 10 degrees is the minimum angulation to define scoliosis, while an angle of greater than 40 to 50 degrees is considered by most to be severe enough to require corrective surgery. Restrictive lung disease and increased alveolar-arterial oxygen difference may be present, as well as pulmonary hypertension as a result of compression of pulmonary vasculature and arterial hypoxia. Formal pulmonary function studies in these patients can guide decisions regarding the extent of surgery and requirement for postoperative ventilatory support. Transthoracic echocardiography can be helpful in assessing the severity of pulmonary hypertension and right ventricular hypertrophy. Correction of spinal deformities can be associated with large intraoperative blood loss, and measures to minimize blood transfusion should be considered. Deliberate controlled hypotension has been employed to limit blood loss but must be used with caution in the older adult, those with cardiovascular disease, or those at risk for ischemic complications[225] and postoperative vision loss. Antifibrinolytic agents are commonly administered to limit blood loss but may need to be avoided in some patients, such as those with a history of thromboembolic events, coronary stents, or renal impairment. TXA is more effective than aprotinin and EACA in reducing total blood loss, intraoperative blood loss, and blood transfusion.[226]

Scoliosis surgery has a variable but high rate of complications, with neurologic injury reported in 0.5% to 7.5% of cases.[227,228] Neurologic deficits can result from migration of bone graft into the spinal canal, penetration of instrumentation, and compression of the nerve roots. Intraoperative neurophysiologic monitoring (IONM) is a valuable technique that can be used in these patients for assessment of the integrity of neuronal structures. IONM is also of value during complex spine surgeries such as revision surgeries in patients with previous thoracolumbar fusion.

INTRAOPERATIVE NEUROPHYSIOLOGIC MONITORING

Somatosensory evoked potentials (SSEP) have been employed since the 1970s to assess the integrity of the larger fiber sensory system during scoliosis correction surgery. Nash and colleagues described a reversible loss of potentials with excessive elongation or derotation of the curve.[229] It was subsequently complemented with motor evoked potential (MEP) monitoring, as clinicians found that patients could become paraplegic despite unchanged intraoperative SSEPs, which monitor conduction of signals through the dorsal column but not the corticospinal tract.[230] MEPs are evoked through application of a train of high-voltage stimuli to electrodes on the surface of the head to activate motor pathways. Stimulation of the white matter produces an orthodromic nerve action potential that can be recorded as direct muscle responses (muscle MEPs) or at the spinal cord level using a flexible electrode once the laminectomy is completed and the dura opened. Direct stimulation of the corticospinal axons generates the D-waves, while stimulation of the axons of the cortico-cortical interneurons with excitatory projections to the corticospinal neurons produces indirect volleys that can be recorded as small deflections of higher threshold and longer latency (I waves).[231] Although D-wave monitoring is limited to the cervical and upper thoracic cord and requires an epidural recording electrode, it is helpful in addition to muscle MEP monitoring because it is resistant to anesthetic depression and neuromuscular blockade and has simple criteria for interpretation. A supplement to SSEP and MEP, triggered electromyography is an excellent technique for determining whether lumbar pedicle screws are properly placed. IONM has been increasingly employed for spine surgeries since its introduction in the 1970s, and is currently recommended for a number of procedures in addition to correction of spine deformities, including procedures with increased risk for SCI (e.g., resection of intramural tumors, unstable spine trauma, Chiari malformation, spinal cord vascular malformations) or risk for root damage (e.g., decompressive surgeries, tethered cord), as well as in patients with significant risk for compression neuropathies. These monitoring modalities are described in detail elsewhere (Chapter 39), but it is important to underscore the role of the anesthesiologist in providing optimal conditions for neuromonitoring, correct and timely detection of changes, and optimization of physiologic parameters to minimize risk for irreversible injuries.

In addition to the anesthetic agents, important physiologic factors such as hypotension, hypoxemia, hypothermia, and hypocarbia may lead to an attenuation of these potentials. In general, it is recommended to use total intravenous anesthesia during IONM, as volatile agents and nitrous oxide reduce the amplitude and increase the latency of the potentials in a dose-dependent manner. If volatile anesthetics are used, it is recommended to keep the concentration below half MAC and avoid any unnecessary or abrupt fluctuations. Opioids and benzodiazepines do not affect the potentials to the same extent, and ketamine or dexmedetomidine[232,233] have been suggested as reasonable complements to the anesthetic regimen. Assuming that the anesthetic effects on these modalities remain unchanged and the patient's physiologic parameters remain stable, an intraoperative loss of SSEPs or MEPs should warn the clinicians of impaired conduction through the dorsal columns or the corticospinal tracts; that is, structural damage has occurred. The damage from surgically-induced spinal cord compression, distraction, or derotation of the spinal column or spinal cord ischemia can be reversible if corrective actions are taken in a timely manner. Therefore, it is important that the surgical, neurophysiologic, and anesthesia teams work together to rapidly diagnose and correct these anatomic or physiologic disturbances. A predetermined checklist for response to IONM changes can guide the clinicians and facilitate rapid interventions aimed at diagnosing and correcting any surgical or physiologic insults. The anesthesiologist should immediately implement measures to optimize cord perfusion (optimize the hemodynamics and correct anemia, temperature and pH, and pCO_2 abnormalities) and be prepared for a possible wake-up test.[234] During a wake-up test, the plane of anesthesia is lightened, and the patient is instructed to make a specified motor response, usually in the lower limbs. If the patient is unable to move his or her legs, corrective measures will need to be instituted immediately. It is, nevertheless, also important to consider the limitations of the wake-up test, including the time needed to reverse any neuromuscular blockade and emerge from anesthesia, dependence on patient cooperation, and risk for complications such as inadvertent extubation, dislodgement of instrumentation, and air embolization during a deep inspiration.

PERIOPERATIVE VISUAL LOSS

An uncommon but devastating complication after spine surgery, perioperative visual loss can be caused by anterior or posterior ischemic optic neuropathy (ION, 89% of the cases), retinal ischemia, cortical blindness, or posterior reversible encephalopathy. In a case-control examination of 80 patients with ION compared with 315 matched control subjects, the ASA Task Force on Perioperative Visual Loss identified risk factors for ION after spinal fusion surgery to be male sex, obesity, Wilson frame use, longer procedural duration, greater estimated blood loss, and lower percent colloid administration.[235] The Task Force issued a detailed practice advisory to assist clinicians in the perioperative management of these patients and with the goal to reduce the frequency of perioperative visual loss.[236] Included are recommendations on perioperative blood pressure management, management of fluids, anemia, and vasopressors, as well as patient positioning and staging of surgical procedures. Of note, a lack of association between deliberate hypotension and perioperative visual loss is discussed by the Task Force, and clinicians are advised to approach this consideration on a case-by-case basis. Central venous pressure monitoring should be considered in high-risk patients and colloids should be used along with crystalloids to maintain intravascular volume in patients who have substantial blood loss. There is no documented lower limit of hemoglobin concentration, but hemoglobin or hematocrit values should be monitored periodically during surgery in high-risk patients with substantial blood loss. Similarly, the decision to use α-adrenergic agonists should be made on a case-by-case basis. Direct pressure on the eye should be avoided, and patients should be positioned so that the head is level with or higher than the heart when possible. Moreover, the high-risk patient's head should be maintained in a neutral forward position without significant neck flexion, extension, lateral flexion, or rotation when possible. Lastly, the use of staged spine surgery procedures reduces the risk of perioperative visual loss and should be considered in high-risk patients.

POSTOPERATIVE PAIN AFTER SPINAL SURGERY

Spinal procedures are associated with a high prevalence of moderate or severe postoperative pain (30%-64%).[237] Timely and effective pain control in this population is important for early ambulation and can facilitate improved functional outcome. The intensity of postoperative pain is directly proportional to the number of vertebrae involved in the surgery and originates from various nociceptors and mechanoreceptors that respond to mechanical irritation, compression, or postoperative inflammation in the vertebrae, intervertebral discs, ligaments, dura, nerve root sleeves, facet joint capsules, fascia, and muscles. It is hence essential that the perioperative team has a pain control plan in place in advance of the surgery, particularly for complex spine procedures involving multiple levels and extensive tissue dissection. The patient should be informed and instructed to set realistic expectations about the type and level of postoperative pain and how to respond when it occurs.

Intravenous opioid analgesics are the most common approach to the treatment of moderate to severe postoperative pain in this group of patients. Their widespread use is, nevertheless, limited by their many side effects, importantly respiratory depression and gastrointestinal side effects. Methadone is increasingly employed in this group of patients and is reported to improve postoperative pain control even when administered as a single bolus (0.2 mg/kg) before surgical incision.[238] A noncompetitive N-methyl-D-aspartate receptor antagonist, methadone is suggested to also reduce opioid tolerance in addition to providing analgesic effects. Ketamine can be used as an adjunct to perioperative opioids, and is demonstrated to reduce postoperative narcotic demand after spinal surgery.[239] NSAIDs have proven efficacy in ameliorating postoperative pain following spinal surgeries,[240] but their use has been limited because of concerns of their effects on bone metabolism and osteoblastic proliferation. Evidence suggests, nevertheless, that impaired bone healing may only be caused by higher doses and longer duration of NSAID administration, and smaller doses for the immediate postoperative period can be considered.[241] Corticosteroids are also occasionally administered, as they are shown to reduce opioid requirements after certain spine procedures, possibly through their antiinflammatory effects as well as the reduction in substance P release. Other options for treating the intensive postoperative pain after spinal surgery include the administration of intrathecal opioids, which has been shown to reduce the cumulative opioid demand. The use of intrathecal opioids is, nevertheless, limited by the associated risk of delayed respiratory depression, requiring close monitoring by skilled personnel. Intrathecal local anesthetic agents are usually not considered for these patients, as they affect the sensory and motor functions, masking any potential postoperative complications. In select patients, however, epidural administration of local anesthetics can provide effective analgesia without compromising the neurologic examination. The epidural catheter can be placed intraoperatively by surgeons under direct vision, and the infusion of local anesthetics can also be initiated after a reassuring neurologic exam has been obtained. Because of the inherent effects of neuraxial anesthesia on the neurologic examination, however, most clinicians choose alternative pain management strategies. More recently, α_2-adrenoreceptor antagonists including clonidine and dexmedetomidine have emerged as effective adjuncts to the aforementioned techniques, enhancing their analgesic properties. Dexmedetomidine is also reported to negate the opioid-induced hyperalgesia that may occur following intraoperative opioid treatment.[242]

65 Geriatric Anesthesia

MILES BERGER, LEAH ACKER, and STACIE DEINER

KEY POINTS

- The proportion of adults over age 70 has increased throughout the world with a corresponding increase in older surgical patients.
- Normal aging is associated with changes in physiology and an increase in many pathologic conditions.
- The number and impact of normal and pathologic conditions varies significantly across elderly individuals.
- Preoperative screening recommendations and guidelines for older patients can provide a useful starting point to evaluate and optimize care.
- Some important geriatric specific areas that are amenable to screening include: cognition, frailty, depression, and polypharmacy.
- Best intraoperative practices follow from an understanding of geriatric physiology and awareness of medications which are contraindicated in the older population.
- Postoperative care tailored to the needs of high-risk adults may benefit the highest risk patients such as palliative care consultation and delirium prevention units.

America is growing old. The number of Americans over age 70 has increased from approximately 15 million in 1975 to over 30 million in 2015, with a corresponding increase in both the percentage of Americans over age 70 and the median American population age (Fig. 65.1A-C). Similarly, worldwide, the number of people over age 70 has increased from approximately 130 million in 1975 to over 400 million in 2015, accompanied by similar increases in the percentage of people over age 70 and the median population age (see Fig 65.1B,C).

The age-related population shifts have translated to similar changes in the population of patients undergoing anesthesia and surgery. In the United States alone, more than 16 million patients over age 60 underwent surgery in 2006. These profound shifts in the American population and the American surgical population have significant implications for anesthesiologists. First, most (though not all) diseases increase in frequency with age. Second, there are age-dependent physiologic changes in virtually every human organ system. These age-dependent physiologic changes typically result in a decrease in the physiologic and functional reserve capacity of each organ system. However, there is considerable variability in the extent of age-dependent changes across organ systems in individual patients, and considerable variability across older patients in the extent of these age-related changes. Indeed, a general principle of geriatric medicine is that as the population ages, the variance of virtually every physiologic measurement increases. Thus while older patients as a whole present additional challenges for perioperative management as a result of increases in comorbid disease and decreases in physiologic reserve, it is important to avoid overapplying these generalizations to individual older patients.

One potential reason that these generalizations apply to varying degrees among older patients is that aging itself involves a plethora of biological pathways (Fig. 65.2) which proceed at varying rates across patients. For example, two 80-year-old patients may show very different telomere lengths, genetic mutation accumulation, and cumulative oxidative stress. Differences in these types of biologic pathways involved in aging have led many to refer separately to chronological age (reflecting the number of years of life) versus biologic age (reflecting the actual accumulation of changes in biologic processes involved in aging).

In this chapter, we discuss common age-dependent physiologic and pathophysiologic changes, and their implications for the preoperative assessment, intraoperative management, and postoperative care of older adults. The significant increases in the age of the American population suggest that the perioperative management of older adults will likely become an increasingly large focus for anesthesiologists. Further, the significant increases in biomedical research expenditures focused on aging and older adults provide reason to hope that this research will lead to improved postoperative outcomes for older adults in the future.

Organ-Specific Age-Related Physiologic and Pathologic Changes

Except for those who exclusively treat pediatric or obstetric patients, most anesthesiologists are geriatric anesthesiologists at least some of the time. Therefore understanding the numerous physiologic changes of aging is critical for caring for the elderly population. Here we discuss these changes by organ system.

CARDIOVASCULAR SYSTEM

In the cardiovascular system, normal aging manifests as changes in vascular and sympathetic tone, the myocardium, the cardiac conduction system, the cardiac valves, and the baroreceptor system.

Vascular Changes With Age

With age, arterial stiffening results in increased afterload, which increases myocardial oxygen consumption and wall stress. Comorbid pathology such as atherosclerosis and decreased β-2 adrenergic vasodilation may compound this effect.

Partially because of age-related vascular changes, the incidence of venous thromboembolism (VTE) increases exponentially with age, affecting up to 600 people over the age of 80 years per 100,000 annually.[1] All three parts of Virchow's classic triad (venous stasis, hypercoagulability, and aberrant blood flow) affect older populations and contribute to this increased risk of VTE. For example, venous

stasis may result from decreased vascular compliance, a low-flow state such as congestive heart failure, immobility, varicose veins, postmenopausal estrogen replacement therapy, and smoking.[2]

Myocardium

In the absence of pathology, systolic function typically remains well preserved throughout life; however, diastolic dysfunction becomes more common. Age-related myocyte death and reciprocal increases in myocyte size lead to myocardial thickening and decreased elasticity.[3] Chronic hypertension can further exacerbate cardiac hypertrophy. Ventricular thickening and stiffening, in turn, impair early diastolic filling, which falls to 50% of its peak by the age of 80 years.[4] In order to maintain cardiac output, geriatric patients are increasingly dependent on preload and atrial kick. Conversely, small decreases in circulating blood volume can lead to inadequate cardiac filling, which can significantly decrease cardiac output.

Cardiac output is also limited by a lower maximal heart rate relative to younger adults[3]; maximal heart rate can be estimated as: HR (bpm) = 220 − age (years). In the absence of arrhythmia, aging of the cardiac conduction system and autonomic system leads to decreased heart rate variability and an increased incidence of ectopic beats.[4] Arrhythmia can dramatically decrease cardiac output in older adults. Atrial fibrillation is the most common arrhythmia, affecting 1 in 10 patients 80 years of age or older.[5] Atrial fibrillation eliminates the atrial kick that decreases left ventricular filling and results in decreased cardiac output.

Cardiac Valves

Normal aging results in a thickened and calcified aortic valve. In addition, the pathologic condition of aortic stenosis is more common with aging and is present in 12.4% of those aged 75 years or older.[5] Patients with aortic stenosis depend on good diastolic volume and normal sinus rhythm to maintain myocardial perfusion. Further, patients with aortic stenosis have increased left ventricular diastolic pressure, which means that they are susceptible to decreased coronary perfusion pressure. To avoid myocardial ischemia in patients with aortic stenosis, it is important to avoid hypotension and tachycardia (which reduces the length of diastole and further impairs coronary perfusion). Even minor left ventricular dilation or a relatively small decrease in left ventricular systolic function can increase the likelihood of intraoperative decompensation.[6]

Sympathetic and Autonomic System

The ability of the sympathetic and autonomic systems to respond to physiologic derangement decreases with age. Decreased β-adrenergic sensitivity leads to a lower maximal heart rate, decreased cardiac output, and limited responsiveness to beta agonists (e.g., dobutamine).[4] Baroreceptor impairment increases the incidence of orthostatic hypotension.[2] For this reason, older patients may be more sensitive to prolonged fasting times and may benefit from drinking clear liquids up to 2 hours before surgery.

RESPIRATORY SYSTEM

As the respiratory system ages, the lungs become less compliant and the muscles involved in respiration weaken. Central responses to hypercapnia and hypoxia are blunted, which puts patients at increased risk for pharmacologic-induced respiratory depression. The incidence of both restrictive and obstructive lung disease and sleep apnea increase with age.

With the aging process, the diaphragm weakens and the chest wall stiffens because of calcification of intercostal cartilage. There are also arthritic changes in the costovertebral joints, weakening and atrophy of the intercostal muscles, and height loss due to osteoporosis and/or kyphosis.[3] Lung compliance increases as elastic recoil decreases despite increased elastin production. Therefore while total lung capacity remains unchanged, functional residual volume increases 5% to 10% per decade, leading to an overall decrease in vital capacity.[7] Aging is also associated with alveolar airspace increases similar to those seen in emphysema, decreased gas exchange, and increased ventilation-perfusion (V-Q) mismatch.[3,7] Mechanical changes include decreased vital capacity, decreased pulmonary reserve, increased work of breathing, and increased residual volume, all of which predispose older adults to atelectasis.[7] Closing capacity, the point at which small airways close, increases with age. Functional residual capacity (FRC) is reduced relative to closing capacity, which may result in atelectasis, pulmonary shunting, and hypoxemia. Certain common intraoperative conditions, such as increased intraabdominal pressure due to carbon dioxide insufflation or Trendelenburg positioning, reduce the FRC and lung compliance. Strategies to minimize atelectasis in the postoperative period include early mobilization/ambulation after surgery, chest physiotherapy, and incentive spirometry.[2]

Compared to younger patients, older patients also have weaker pharyngeal muscles, decreased clearance of secretions, decreased mucociliary transport, less efficient coughing, decreased esophageal motility, and less effective protective upper airway reflexes.[7] Together, these factors place the older population at increased risk for aspiration and postoperative pneumonia. Anesthesiologists can implement four specific strategies to reduce the risk of aspiration and other pulmonary complications. First, using neuraxial or regional anesthesia with minimal sedation in lieu of general anesthesia (when possible) can reduce the risk of aspiration by reducing anesthetic-induced interference with the cough reflex. Second, avoiding intermediate and long-acting neuromuscular blocking agents, and ensuring adequate reversal of neuromuscular blockade, can also help reduce aspiration and postoperative pneumonia risk.[2] Residual neuromuscular blockade is a particular concern in older patients with reduced pulmonary function.[7] Third, respiratory depressants such as opioids can lead to hypoventilation and respiratory acidosis, which further potentiates the effects of neuromuscular blocking agents.[7] When appropriate, opioid-sparing analgesic strategies can be helpful in older patients.[8] Fourth, neutralization of stomach acid with nonparticulate antacids (such as sodium citrate) can be helpful in preventing chemical pneumonitis and pulmonary injury in case aspiration does occur.

In addition to mechanical changes, older adults have an approximate 50% decrease in the respiratory response to hypoxia and hypercarbia, which is even more pronounced during sleep.[9] Some geriatric patients may not awaken from rapid eye movement sleep until oxygen saturation decreases significantly (e.g., to 70% or lower).[7] The most common sleep-related respiratory derangements in older adults is sleep apnea, which may affect 50% to 75% of patients over age 65.[7,10] Older patients tend to have decreased hypopharyngeal and genioglossal muscle tone, which predisposes them to upper airway obstruction, particularly during sleep.[7] Patients can be screened preoperatively for obstructive sleep apnea (OSA) using one of several screening questionnaires such as the STOP-Bang, Berlin, or American Society of Anesthesiologists (ASA) questionnaires.[11] Patients with OSA should be recognized as having a potentially difficult mask airway and postoperatively may benefit from continuous positive airway pressure[11] and opioid-sparing management.[12]

RENAL SYSTEM

After 50 years of age, average kidney weight decreases from approximately 250 g to 180 g, mostly as a result of cortical atrophy from glomerulosclerosis. Along with this loss of renal cortex, the glomerular filtration rate (GFR) decreases by about 1 mL/min/m^2 per year starting at 40 years of age.[3] Chronic diseases frequently found in the older population (e.g., hypertension, diabetes mellitus, and atherosclerosis) can exacerbate this normal age-related decline in renal function. Although elderly patients typically have normal serum creatinine levels, they also tend to have decreased lean muscle mass and lower creatinine overall. Therefore a "normal" serum creatinine in an older patient may belie a reduced glomerular filtration reserve and obscure the resulting renal sensitivity to ischemic and nephrotoxic injuries. Specifically, in the setting of reduced GFR, medications that are excreted through the kidney may accumulate if the dose is not appropriately adjusted.

In addition to reduced GFR, blunted responses to aldosterone, vasopressin, and renin also reduce the older patient's ability to adjust volume status and may result in electrolyte and acid-base derangements. In particular, older adults are susceptible to dysnatremias; hyponatremia affects 11% of the geriatric ambulatory community and 5.3% of hospitalized geriatric patients. Hypernatremia affects 1% of hospitalized patients age 60 and older.[13] Further, because older adults often have inappropriate sodium excretion, they are particularly prone to hypotension and acute kidney injury in the setting of hypovolemia.[13]

The incidence of urologic disease (i.e., bladder and prostate) also increases with age. The incidence of postoperative urinary retention increases in older men and women.[14] This is an important point to recognize because discomfort due to urinary retention can be a common cause of postoperative agitation. Urinary tract infections (UTI) also increase in incidence in older men and women.[2] Elderly women may have skin breakdown in the genital area because of vaginal atrophy from decreased estrogen,[15] which increases the risk of UTI.[16] In addition, the incidence of pelvic prolapse in women increases with age and also increases the risk of UTI.

GASTROINTESTINAL AND HEPATIC SYSTEMS

The size and function of the liver decrease with age, which affects hepatic drug metabolism. After age 50, the liver decreases from 2.5% of total body mass to 1.5% in part due to fewer hepatocytes and decreased blood flow.[3] Despite having fewer hepatocytes, healthy older adults typically have normal liver synthetic function, though they have reduced reserve under stress.[3] Similarly, hepatic blood flow decreases with age such that the average 65 year old has 40% less hepatic blood flow than the average 25 year old.[17] Older populations may more slowly metabolize drugs that are cleared by phase-1 pathways (e.g., oxidation, reduction, and hydrolysis through the cytochrome P450 system) because of decreased hepatic blood flow,[18] but phase II metabolism (e.g., acetylation and conjugation) does not seem to be affected by age.[17] Anesthesiologists should be aware that older adults are slower at clearing high extraction drugs whose clearance depends directly on hepatic blood flow (e.g., ketamine, flumazenil, morphine, fentanyl, sufentanil, and lidocaine).[17]

The incidence of postoperative nausea and vomiting decreases with age, which is fortunate because many antiemetics act through anticholinergic and/or antihistaminergic mechanisms, which can cause altered mental status and delirium. The Beers criteria recommend against most of these medications as they increase the risk of delirium.[2] Specifically, the Beers criteria recommend avoiding prochlorperazine, promethazine, metoclopramide (except in the setting of gastroparesis), and corticosteroid prophylaxis.[2,19] The 5-HT3 receptor antagonists (e.g., ondansetron), are a better choice for older adults, although the 5-HT3 antagonists contribute to QTc interval prolongation.[2]

The incidence of some hepatic and gastrointestinal pathologies increases with age. For example, the incidence of nonalcoholic fatty liver disease (NAFLD) increases with age, affecting nearly half of geriatric patients; however, in contrast to younger populations, it is unclear whether NAFLD is associated with metabolic syndrome, cardiovascular disease, or cirrhosis when it is first diagnosed at an advanced age.[20] That said, as the obese diabetic patients with NAFLD age and become geriatric patients, they have an increased risk of complications, such as severe hepatic fibrosis, hepatocellular carcinoma, and cryptogenic cirrhosis.[20] Whereas hepatic pathology certainly impacts anesthetic management, other common gastrointestinal disorders of older adults, such as diverticulosis and cholelithiasis, typically do not.

MUSCULOSKELETAL SYSTEM

As with other organ systems, the aging musculoskeletal system undergoes changes relevant to anesthesiologists. Among the well-functioning older adult, lean muscle mass declines by roughly 1% annually while muscle strength declines by roughly 3% annually, meaning muscle function and quality decreases faster with age than muscle quantity does.[21] Maintaining strength in the perioperative period is critical in older people. Declining muscle strength is associated with increased mortality risk,[22] and older adults lose muscle mass much faster than their younger counterparts. For example, healthy older adults who were placed on bedrest for 10 days experienced greater loss of muscle mass than healthy younger adults who were placed on bed rest for 28 days.[23]

Decreased lean muscle mass can prove misleading among older patients, whose weight may remain stable, while their total body fat increases and their subcutaneous (insulating) fat reserves decrease. A 10-year longitudinal study of older adults showed a 23% per decade decline in subcutaneous fat with a concurrent average 11% per decade increase in total body fat.[24] Diminished subcutaneous fat thickness and age-related dysregulation of cutaneous circulation help to explain why older patients are much more prone to temperature dysregulation intraoperatively even though the basal core temperature of the elderly (aged 65-95) is only about 0.4°C (0.7°F) lower than that of other adults (aged 25-64).[25] Age-related dysregulation of the cutaneous microcirculation also contributes to impaired wound healing. Anesthesiologists can optimize surgical healing in this population by maintaining adequate hydration, normothermia, and good tissue oxygenation.[26]

Along with age-related changes in the muscles and skin, aging affects the skeletal system as well. Osteoarthritis affects about half of those aged 75 and older and can lead to limited joint mobility in older patients. Anesthesiologists should be aware of this and inquire about this with older patients to avoid exacerbating preexisting joint issues while positioning the patient in the operating room.[27]

CENTRAL NERVOUS SYSTEM

Changes in the aging central nervous system can give rise to a host of age-related concerns, such as cognitive decline, memory loss, sleep derangements, dementia, movement disorders, depression, and an increased risk of delirium. Although the number of neurons in the brain does not decrease in normal aging, older brains have fewer dendrites and synapses, which contributes to decreased brain volume and to decreased neuronal connectivity, particularly in the hippocampus, frontal/prefrontal cortex, and the temporal lobe.[28] Specifically, magnetic resonance imaging studies have shown that cortical gray matter thins at a rate of 0.5% to 1% per year in the geriatric brain.[29] Further, age-related dysregulation of neuronal transmission, baseline neuronal firing, calcium metabolism, and gene expression diminishes both connectivity and plasticity.[30] Functionally, these physiologic changes contribute to normal, age-related cognitive decline in many domains such as executive function, cognitive processing speed, working and spatial memory, and maintenance of circadian rhythm. Of particular relevance to anesthesiologists, these age-dependent decreases in cognitive reserve may manifest as increased sensitivity to anesthetic medications, an increased risk of postoperative cognitive dysfunction and delirium, and a decrease in function.

Specifically, in dementia, the decline in memory and cognition becomes severe enough to interfere with daily activities whereas in mild cognitive impairment, cognitive decline is measurable and noticeable, but does not interfere with one's ability to perform daily activities. Frank neuron loss typically occurs in dementia, regardless of the dementia subtype. In Alzheimer disease, a complex interplay between abnormal tau and beta-amyloid proteins seems to precipitate global neuronal cell death while in vascular dementia, neuronal cells die because of hemodynamic compromise, leading to a step-wise decline in cognitive function. Finally, in Lewy body dementia abnormal α-synuclein deposits give rise to neuronal death. Overall, dementia increases dramatically in prevalence with advancing age in a step-wise manner (Fig. 65.3), affecting nearly two-thirds of patients over the age of 90 years.[31]

Dementia presents challenges for anesthesiologists, particularly regarding pain management. For example, patient-controlled analgesia may not be an option. Opioid administration is often difficult to titrate in these patients, and patients may not be able to cooperate with regional anesthesia. Further, patients with dementia may also develop concurrent delirium, which can be difficult to disambiguate from underlying dementia. Similarly, Parkinson disease presents a particular challenge for the anesthesiologist. Patients with Parkinson disease are more prone to developing immobility and thus deep venous thrombosis; dysphagia and respiratory dysfunction and thus aspiration and pneumonia; urinary retention and thus UTI; and psychiatric complications and thus delirium.[32] Drug interactions can be a particular concern in patients with Parkinson disease. For example, many antiemetic drugs such as metoclopramide and promethazine antagonize dopamine and may worsen extrapyramidal symptoms. Inhibitors of the enzyme monoamine oxidase (MAO)-B, which are frequently used in Parkinson disease, can predispose patients to serotonin syndrome, particularly if used in conjunction with certain opiates such as tramadol.[33] Propofol can induce dyskinesia in this population,[34] which can be managed with dexmedetomidine.[33]

Mood disorders, particularly depression, are often underrecognized in older adults. Minor depression affects approximately 7.7% of geriatric primary care patients, approximately 14.4% of geriatric patients in hospital settings, and nearly 20% of those with minor cognitive impairment.[35] Depression predisposes patients to postoperative cognitive dysfunction (POCD), in-hospital delirium, major adverse cardiac events, increased postoperative analgesic use, and suboptimal postoperative outcomes.[36-38] Discussion of mood symptoms prior to anesthesia can help to inform perioperative management and the use of antidepressant medications. Typically, antidepressants are continued during the perioperative period because of the risks of "discontinuation syndrome" and because of their benefits for pain management[39]; however, MAO inhibitors can lead to severe hypotension in the setting of sympathetic stimulation or in conjunction with sympathomimetic drugs. Even selective serotonin reuptake inhibitors, the most commonly

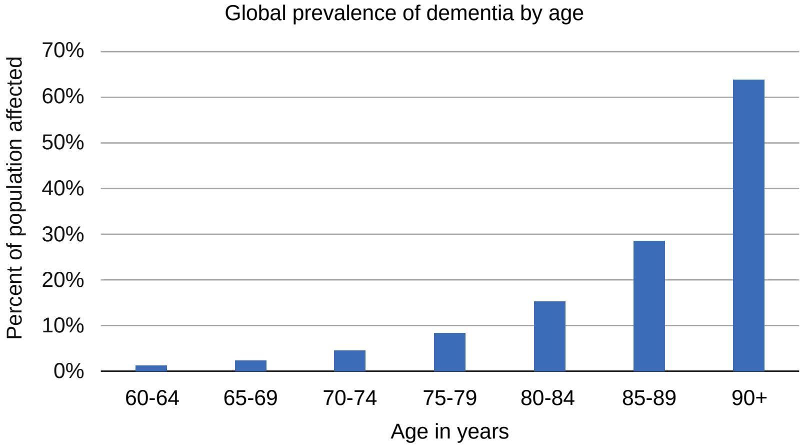

Fig. 65.3 Global prevalence of dementia by age. (Redrawn from Prince M, Bryce R, Albanese E, et al. The global prevalence of dementia: a systematic review and metaanalysis. *Alzheimers Dement.* 2013;9:63–75.)

used and "safest" antidepressants, have been associated with a higher risk of in-hospital mortality, bleeding, and readmission.[40]

Finally, delirium and POCD are two common postoperative complications in older patients. Each of these topics have dedicated chapters in this text, so they are only briefly reviewed here. Delirium, which affects about 10% of older postoperative patients overall and 60% to 80% of intensive care unit (ICU) patients, manifests as acute, fluctuating confusion with altered attention and awareness that cannot be better explained by preexisting or developing dementia. Common delirium screening tools include the Confusion Assessment Method (CAM) and the CAM-ICU for ventilated ICU patients. Few treatments for delirium have proven efficacious; however, management of underlying medical conditions (e.g., electrolyte imbalances, infections), modifying risk factors (e.g., reducing sleep deprivation, increasing mobility, giving patients their glasses and hearing aids, ensuring good hydration), and avoiding or limiting medications known to trigger delirium (e.g., benzodiazepines, dihydropyridines, antihistamines, opioids) may prove beneficial. In contrast to delirium, POCD is a syndrome defined by worsening performance on neuropsychologic tests postoperatively compared to a perioperative baseline.[41] Overall, this decline in cognitive performance across multiple domains presents days to weeks after surgery and is associated more strongly with age than any other risk factor.[42] By and large, POCD resolves within months of both cardiac and noncardiac surgery; however, individual patients may follow different trajectories with declines remaining up to 5 years or longer.[41]

Preoperative Assessment

Preoperative assessment of the geriatric surgical patient follows the general principles of good medical care while adding special attention to issues that may have greater incidence or impact in older adults. In 2014, the American College of Surgeons (ACS) convened an expert panel and published a consensus statement with evidence-based recommendations.[43] Good medical care–type recommendations include the use of the American College of Cardiology and American Heart Association algorithm for patients undergoing noncardiac surgery,[44] ordering appropriate laboratory tests based on comorbidity, and determination of the risk for postoperative pulmonary complications. Geriatric-specific evaluation includes assessment of the patient's cognitive ability, identifying the risk for postoperative delirium (covered in detail in Chapter 82), documentation of functional/frailty/fall-risk status, monitoring for polypharmacy, screening for depression and alcohol use, understanding patient's expectations, and advanced directives.

COGNITIVE ASSESSMENT AND DELIRIUM RISK

In the immediate perioperative period, occult preoperative cognitive impairment in older adults is common; the incidence is more than 20% of patients over 65 years of age presenting for presurgical testing with the highest prevalence in the oldest patients.[45] However, talking with patients and families about cognitive health before and after surgery is a new challenge for anesthesiologists. In 2016, the ASA launched the Brain Health Initiative, which is a "low barrier access program to minimize the impact of preexisting cognitive deficits, and optimize the cognitive recovery and perioperative experience for adults 65 and over…." The basic principles of the program include screening for preoperative cognitive impairment and that anesthesiologists lead discussions regarding the potential for postoperative delirium and cognitive dysfunction.

The cognitive assessment of patients prior to surgery can be challenging. In-depth neuropsychiatric testing is not practical for most pretesting centers since it often involves an hour or more of tests administered by a trained individual. More practical for the presurgical arena is the use of brief screening tools that are meant to identify patients who are likely to have cognitive impairment (Table 65.1). A recent large study suggests that cognitive screening in a pretesting clinic is practical and well accepted by patients and staff members.[45] An obvious but difficult question for anesthesiologists is how to proceed when a patient is identified as likely to have cognitive impairment. Informing patients and offering

TABLE 65.1 Brief Cognitive Screening Tools

Tool/Test	Advantage	Disadvantage	Sensitivity (%)*	Specificity (%)*	Time to Administer
Minicog[45,49,75-77]	Brief, minimal language, education, race bias	Use of different word lists may affect scoring	76-100 (54-100)	54-85.2 (43-88.4)	2-4 min
Montreal Cognitive Assessment (MoCA)[78-81]	Can identify mild cognitive impairment, available in multiple languages	Education bias, limited published data	n/a	n/a	10-15 min
Mini-Mental State Examination (MMSE)[77,82,83]	Widely used and studied	Subject to age and cultural bias, ceiling effects	88.3 (81.3-92.9)	86.2 (81.8-89.7)	7-10 min
Clock-drawing Test[77,84]	Very brief	No standards for administration and scoring	67-97.9 (39-100)	69-94.2(54-97.1)	<2 min
Verbal Fluency Test[77,85]	Brief	Cut point not obvious	37-89.5 (19-100)	62-97 (48-99)	2-4 min
Cognitive Disorder Examination (CODEX)[86-88]	Brief	Less well-studied	81-93	81-85	≤3 min

*Sensitivity and specificity values are for the detection of cognitive impairment or dementia—see references for more detail.

them postsurgical follow-up with an expert in cognition is important. The same study showed that patients believe that screening before surgery is important and that they want to know their results. Baseline cognition is also important for delirium-risk stratification; patients with cognitive impairment are at higher risk and therefore may benefit the most from delirium prevention programs. Additionally patients, caregivers, and the perioperative team should have this information since these patients are more likely to require a higher level of care after surgery such as a skilled nursing facility.[46] The ACS guidelines strongly recommend performing cognitive assessment early in the patient evaluation because impairment suggests that medication information and functional status reporting may be unreliable, although in the latter there is some evidence to the contrary.[47]

Although preoperative cognitive impairment is a risk factor for the occurrence and severity of postoperative delirium, it is not the only risk factor.[48] There are several delirium-risk prediction indices and examples of two delirium prediction tools are listed in Table 65.2. Whereas each index is a bit different, most include age, cognitive status before surgery, then some index of medical illness, and the invasive nature of the surgery.[49-51]

FUNCTIONAL/FRAILTY SCREENING

Frailty is a common and morbid condition found with a higher prevalence in older adults before surgery (25%-56%)[52,53] than in community-dwelling elders (10%).[54] Frailty has been conceptualized in two major ways: one includes decreased reserve to physiologic stress and is characterized by decline across organ systems; and the other is an accumulation of deficits, that is, the accumulation of comorbid states that can result in overall physiologic vulnerability. Frailty has been shown to correlate with poor postoperative outcomes (death, complications) in a wide range of major surgeries.

Although frailty is a geriatric syndrome it does not need to be measured by a geriatrician. The classic frailty phenotype measured by Linda Fried[55] did require expertise; however, there are now several validated frailty screening tools.[56] It is not clear which of the screening tools best measures frailty and the answer may vary for different populations and settings.[53,57] For instance, a frailty screen that includes grip strength may not be best suited for a cervical spine population that often has cervical myelopathy. The preoperative testing facility may dictate the type of assessment possible; some preoperative clinic areas are not suitable for a 5-meter gait speed test. Table 65.3 has examples of frailty assessment tools.[58]

Frail and/or prefrailty has been shown to correlate strongly with complications and mortality in a wide range of surgeries. Ideally frailty can inform procedure selection, patient-doctor conversations, and discharge planning. Prehabilitation including nutritional support and exercise may be considered, although exact protocols have not been well vetted. Certainly, malnutrition is more common in preoperative older surgical patients and is associated with postoperative complications and increased length of stay.[59] Frailty is also a risk factor for delirium and frail patients may benefit from multidisciplinary interventions to support orientation, early mobilization, and maintenance of sleep-wake cycles. Preoperative identification of frailty for the surgical team has been shown to increase utilization of palliative care consults and improve patient outcomes.[60,61]

PALLIATIVE CARE

Palliative care focuses on relief of suffering and improvement of quality of life in patients with serious but not necessarily terminal illness. The use of palliative care expert consultants to support patients undergoing surgical intervention is relatively new.[62] Palliative care was recognized as a medical specialty in 2006 and certified its first physicians in 2008. In 2012 there were fewer than 100 surgeons and anesthesiologists certified in palliative care, and although the fellowship spots are increasing, there is a relative shortage.[62] This implies that most palliative care for surgical patients is provided by nonsurgical subspecialty providers. Research regarding the use of surgery

TABLE 65.2 Validated Risk Models for Prediction of Postoperative Delirium in Cardiac and Noncardiac Surgery Patients

Authors	Patients and Surgery	Risk Factors	Results
Rudolph and colleagues[96]	Cardiac surgery ($n = 122$ for derivation cohort, $n = 109$ for validation cohort)	▪ Previous stroke (1 point) ▪ Geriatric Depression Scale >4 (1 point) ▪ Abnormal albumin (1 point) ▪ MMSE 24-27 (1 point) or MMSE <24 (2 points)	In the validation cohort, the cumulative incidence of delirium for each point level was as follows: 0 points, 18%; 1 point, 43%; 2 points, 60%; and ≥3 points, 87%

and palliative care is relatively new; however one study found that frailty screening in an elderly veterans' hospital surgical cohort increased preoperative palliative care consultation and was associated with a 33% reduction in 180-day mortality.[61]

POLYPHARMACY

Preoperative assessment of medications is very important; studies suggest that the incidence of discrepancies between surgical and anesthesiology assessments are greater than 70%.[63] The advent of computerized medical records can be helpful or harmful as medications which are not deleted from the record may continue to appear as current. Therefore medical reconciliation at admission and discharge is required to assure up-to-date information. Best practice may include working with pharmacists to review patient medications for polypharmacy and potential drug interactions and contraindicated medications for older adults. These include the American Geriatric Society's Beers Criteria for Potentially Inappropriate Medication Use in Older Adults.[64] The list includes several medications commonly seen in anesthesia order sets: meperidine, scopolamine, benzodiazepines (Table 65.4).

DEPRESSION AND ALCOHOL SCREENING

Depression and alcohol abuse each have approximately a 10% incidence in older adults, and each are associated with a more difficult postoperative course. The former is associated with greater pain perception and increased need for postoperative analgesics, and the latter postoperative complications such as pneumonia and sepsis.[65] Depression can be assessed using tools such as the Patient Health Questionnaire -2[66] which asks:

"In the past 12 months have you ever had a time when you felt sad, blue, depressed or down for most of the time for at least 2 weeks?"

"In the past 12 months have you ever had a time lasting at least 2 weeks when you didn't care about the things you usually cared about or when you didn't enjoy the things that you usually enjoyed?"

"Yes" to either constitutes a positive screen which needs further evaluation.

The classic screening tool for alcohol use is the modified CAGE questionnaire which has been validated for use in older adults.[67,68] The questionnaire consists of four questions:

- Have you ever felt you needed to cut down on your drinking?
- Have people annoyed you by criticizing your drinking?
- Have you ever felt guilty about drinking?
- Have you ever felt you needed a drink first thing in the morning (Eye Opener) to steady your nerves or get rid of a hangover?

"Yes" to any question triggers consideration for perioperative prophylaxis for withdrawal syndromes, supplementation of folic acid and thiamine, and consideration of the need for a detoxification protocol supervised by an addiction specialist.[43]

CAPACITY/ADVANCED DIRECTIVES/ EXPECTATIONS/SUPPORT

Capacity

In working with older adults, it is important to understand whether they retain the capacity for medical decision making. Cognition may overlap with capacity but is not the same thing. Many patients with mild cognitive

TABLE 65.4 Common Medications in the Perioperative Period With Potential Neurological Side Effects That Are Also on the 2012 Beers Criteria List for Potentially Inappropriate Medication Use in Older Adults

Drug	Rationale
Diphenhydramine	Highly anticholinergic; may increase confusion
Hydroxyzine	Highly anticholinergic; may increase confusion
Scopolamine	Highly anticholinergic
Amitriptyline	Highly anticholinergic; sedating
Antipsychotics	Increased risk of stroke and mortality in persons with dementia
Benzodiazepines	Older adults have increased sensitivity and decreased metabolism; risk of cognitive impairment, delirium, and falls
Metoclopramide	Extrapyramidal side-effects; risk may be increased in older adults
Pethidine	Not effective analgesic; may cause neurotoxicity
Pentazocine	May cause central nervous system adverse events, including confusion and hallucinations
Neuromuscular blocking drugs	Poorly tolerated by older adults, with anticholinergic adverse effects

From Brown C IV, Deiner S. Perioperative cognitive protection. *Br J Anaesth*. 2016;117(S3):iii52–iii-63.

impairment may retain capacity. The legal definition of capacity includes[69]:

- Ability to communicate treatment choice.
- Comprehension of the information given by the physicians.
- Able to voice understanding of their medical condition, options for therapy, and outcomes.
- The ability to conduct a rational discussion regarding their treatment options.

Patients may retain capacity for some decisions and not others, or not have capacity for medical decision making entirely. In the case where an older patient does not have capacity for medical decision making it is important to understand whether there is someone who has power of attorney. Working with the power of attorney and with respect to the patient's wishes, the older adult can be included in the discussion as appropriate.

Shared Decision Making/Expectations

Advanced directives are documents that provide information on patient wishes for healthcare decisions in the event that they cannot participate in decision making (Fig. 65.4). Discussion of advanced directives is an important part of understanding and respecting patient's goals of care. The ASA guidelines state that Do-Not-Resuscitate orders should not be automatically suspended in the perioperative period. According to the patient's wishes they may choose to accept limited attempts at resuscitation in the case of certain procedures or in certain contexts (e.g., quickly and easily reversible adverse events such as a drop in blood pressure or need for transfusion). As administration of anesthesia may involve procedures that overlap with resuscitation, the nuances of which procedures are acceptable to the patient and/or surrogate should be reviewed before the procedure. The anesthesiologist should discuss and document any modification of the directive, such as the patient's wishes in the event of complications and plans for postoperative care. These should be communicated to the surgeon before the procedure; the case of conflict between providers may require institutional clarification.

Intraoperative Management Considerations for Older Adults

Once preoperative assessment and preprocedure consent have been completed, the anesthesiologist's task is to design an intraoperative anesthetic plan for each individual older patient that provides adequate intraoperative and postoperative analgesia, effective sedation or amnesia, hemodynamic stability, and optimal operating conditions (i.e., surgical site immobility) for the surgical team. It is difficult to make general intraoperative recommendations for older adults, partly because of the wide heterogeneity in organ system reserve and overall functional status across older patients. The anesthetic plan for each individual older patient should be based on each patient's comorbid illnesses, organ system reserve, and overall functional status.

Nonetheless, a large body of research has examined specific anesthetic techniques in older adults, and several general recommendations can be made (Box 65.1). Likely due to decreased physiologic reserve, many older adults require more careful intraoperative management than younger, healthier patients with greater physiologic reserve. Thus drug administration, "anesthetic depth," and hemodynamic status should be titrated even more carefully in older adults than in other patient groups. Increased monitoring, such as electroencephalogram-based anesthetic titration, may be helpful in this regard. Overall, no specific anesthetic drug or technique (e.g., regional versus general anesthesia) has been consistently associated with an increased (or decreased) incidence of postoperative neurocognitive disorders, such as delirium or postoperative cognitive dysfunction in older patients.

Postoperative Concerns

Best practice guidelines from the ACS for the postoperative period include adequate pain control and a geriatric-focused prevention checklist that includes: delirium, pulmonary complications, falls, postoperative UTIs or urinary retention, pressure ulcer prevention, and care transitions. There are no specific recommendations for care of the older adult in the recovery room. However, the physiology of aging and common diseases suggests that these patients are at higher risk for desaturation (because of decreased closing capacity and a tendency toward atelectasis) and aspiration (for example, due to a less vigorous ability to cough). Maximizing the patient's ability to take deep breaths by elevating the

ADVANCE DIRECTIVE ACTIVATION

(a licensed physician or mental health professional must complete this form)

Patient Name: ____________________________________ Medical Record #:_______________
Date: ____

Following appropriate evaluation and/or discussion with the above-named patient, the following has been determined: *(initial only one)*

________ This patient is *now* unable to adequately comprehend his/her medical condition and/or is unable to provide informed consent for necessary treatment(s).

________ This patient is *intermittently* unable to comprehend his/her medical condition and/or to provide informed consent for necessary treatment(s). An advance directive agent/proxy is needed on an emergent/stand-by basis.

________ This patient *has* decisional capacity, but due to the burdens of illness and/or informed consent criteria, he/she *elects to defer* decision-making to his/her agent/proxy as named in a valid advance directive document on file at this medical facility.

Reliance on an advance directive agent is expected to be:

(initial only one)

________ Temporary. The patient will be continuously reevaluated, and the agent/proxy will be notified if the patient regains decision-making capacity and/or desires to resume a decision-making role.

________ Permanent. The patient's loss of decision-making capacity is expected to be enduring. Reevaluation of decision-making capacity will take place only if the patient's cognitive condition substantially and unexpectedly changes.

An agent/proxy named in this patient's advance directive has been notified of the above on this date at the following time: _________. He/she has been advised of the patient's overall medical condition, and agrees to remain reasonably available for ongoing consultation and decision-making participation. In the event he/she will not be available, he/she agrees to notify the facility staff and any alternate agent/proxy in advance.

Signed: ____
(Attending physician or other health care provider)

head of the bed and providing adequate but not excessive pain management may combat these issues.

The issue of pain perception and tolerance has been a controversial area of study. A recent meta-analysis suggests that aging has no strong effect on pain tolerance although there may be some decreased sensitivity for low-intensity pain, most specifically to heat.[70] Therefore it is important to aggressively monitor and treat older adults for pain and regularly reassess their condition to avoid oversedation. In the case of patients with dementia, and/or nonverbal patients, it may be important to employ tools that can help identify pain behaviors, such as the Pain Assessment in Impaired Cognition tool. Measures for adequate pain control include the judicious use of multimodal therapy and regional anesthesia. Care must be taken to avoid use of Beers list medications, which include gabapentin and long-acting opioids.

Delirium prevention is covered in Chapters 23, 52, and 80. Some general strategies are listed in Table 65.5. In brief, multidisciplinary nonpharmacologic programs have been the most successful efforts to reduce delirium. The

BOX 65.1 **Delirium Prevention Strategies**

- Education targeted to healthcare professionals about delirium
- Multicomponent, multidisciplinary nonpharmacologic interventions that may include:
  - Daily physical activity
  - Cognitive reorientation
  - Bedside presence of a family member whenever possible
  - Sleep enhancement (e.g., nonpharmacologic sleep protocol and sleep hygiene)
  - Early mobility and/or physical rehabilitation
  - Adaptations for visual and hearing impairment
  - Nutrition and fluid repletion
  - Pain management
  - Appropriate medication usage
  - Adequate oxygenation
  - Prevention of constipation
  - Minimization of patient tethers whenever possible (e.g., Foley catheters, periodic removal of sequential compression devices, electrocardiogram cords)

program most commonly used is the Hospital Elder Life Program (HELP), which includes reorientation, mobilization, and promotion of regular sleep-wake cycles. HELP has been shown to reduce delirium, cognitive and functional decline, and to be cost effective.[71,72] Antipsychotic medication should only be used to treat agitated delirium in the patient who may be a danger to self or staff and never used as prophylaxis.[64] Benzodiazepines are contraindicated for this situation and may worsen a delirium episode.

Outcomes

As previous editions noted, the goal of surgery for the older adult includes preserving independence and function while treating the presenting condition. Large administrative datasets are just beginning to collect enough in-depth information to help practitioners understand outcomes in greater depth than 30-day mortality. The National Surgical Quality Improvement Database launched a

TABLE 65.5 Recommended Intraoperative Practices for Older Adults (By Systems)

	Practice Suggestion	**Rationale**
GENERAL PHARMACOLOGIC POINTS		
	Careful drug titration	Age-related changes in the volume of distribution for many drugs, albumin concentration, and other changes cause changes in the pharmacokinetics and pharmacodynamics of many anesthetic drugs[95]
NERVOUS SYSTEM		
	Consider using EEG-based anesthetic dosage titration	Reduces postoperative delirium rates[89-93]; may reduce postoperative cognitive dysfunction rates[89,91]
	Consider titrating intraoperative hemodynamics and transfusion management in response to cerebral oximetry	May reduce postoperative delirium rates[91,92]
	Reduce MAC fraction	MAC and MAC-awake decline by 6% per decade after age 30; increased MAC fraction is associated with increased rates of PONV, POCD, delirium[92,94]
	Reduce opioid administration	Opioid sensitivity increases with age; reducing opioid dosage may reduce postoperative respiratory depression
	Minimize dosage of neuromuscular blocking agents, and/or ensure that they are fully reversed (i.e., Train-of-four ratio >90%) prior to extubation	Reduces postoperative pulmonary complications
	Avoid use of drugs on Beers list (see Table 65.4)	Reduces rates of postoperative delirium, altered mental status
CARDIOVASCULAR		
	Avoid hypotension	Helps reduce rates of acute kidney injury; helps ensure adequate coronary perfusion
	Avoid hypertension	Helps reduce myocardial ischemia by avoiding excessive afterload and resultant increases in myocardial oxygen consumption (i.e., myocardial workload)
SKIN		
	Pad skin carefully	Helps avoid pressure ulcers
MUSCULOSKELETAL		
	Pad joints and exposed nerves (e.g., ulnar nerve)	Helps minimize the increased risk of intraoperative nerve injury, which is increased in elderly due to loss of soft tissue/padding

POCD, Postoperative cognitive decline; *PONV*, postoperative nausea and vomiting.

geriatric-specific data collection in January 2014. This enhanced collection included risk factors and outcomes in areas such as cognition, decision making, function, and mobility. An early report demonstrated that among general vascular and orthopedic surgery, functional decline occurred in 42.9% percent of patients.[73] Factors associated with an increased risk of functional decline included cognitive impairment, need for surrogate consent, use of mobility aids, and a history of falls.[74] While some of these factors are currently part of a preoperative evaluation, others (cognitive screening) are not often evaluated. More work is needed to employ geriatric screening and to understand how preexisting states impact postoperative outcomes. While many conditions may not be amenable to change, it is clear that understanding risk is an important part of informed consent, impacts surgical decision making, and postoperative support.

Acknowledgment

The editors and publisher would like to thank Drs. Frederick Sieber and Ronald Pauldine for contributing a chapter on this topic in the prior edition of this work. It has served as the foundation for the current chapter.

Anesthesia for Trauma

SAMUEL MICHAEL GALVAGNO JR., MARC P. STEURER, and
THOMAS E. GRISSOM

KEY POINTS

- Perioperative anesthesia care for patients who have undergone acute trauma depends on an understanding of trauma system design and surgical priorities.
- Successful emergency airway management is based on having a clear plan, such as the American Society of Anesthesiologists algorithm for difficult airways adapted for trauma. In general, rapid sequence induction of anesthesia and in-line cervical stabilization, followed by direct laryngoscopy or video laryngoscopy, is the safest and most effective approach. The use of cricoid pressure is controversial and is no longer a class I recommendation.
- Recognition of hemorrhagic shock is at the center of advanced trauma life support. Hemorrhagic shock indicates the need for rapid operative treatment, with the possibility of a damage control approach. Although establishing an adequate airway remains the initial priority, obvious hemorrhage should be concurrently addressed through immediate application of tourniquets or direct pressure.
- Resuscitation during acute hemorrhagic shock has undergone a significant change in emphasis. Current recommendations are to allow permissive hypotension during active bleeding by limitation of crystalloid infusion. Recognizing the impact of early coagulopathy in trauma, a "hemostatic" resuscitation should be employed, with an emphasis on maintenance of blood composition by early transfusion of red blood cells, plasma, and platelets, and viscoelastic monitoring when available.
- Management of patients with severe traumatic brain injury requires monitoring and maintenance of cerebral perfusion and oxygenation for successful operative and intensive care management.
- Operative timing for the surgical management of traumatic injuries, including orthopedic trauma, must be balanced between early definitive repairs and the potential for worsening overall physiologic stress.
- Trauma anesthesiology includes a substantial component of critical care practice (see also Chapter 83).

Introduction

EPIDEMIOLOGY

Death and disability caused by injuries remain a public health threat worldwide. For both children and adults younger than age 45, traumatic injuries remain the leading cause of death in the United States.[1,2] Moreover, injury-associated deaths have substantial economic consequences; the total estimated lifetime medical and work-lost costs associated with fatal injuries has been reported to be over $240 billion and is projected to increase.[1,3] Unintentional injuries (i.e., injuries due to motor vehicle accidents, falls) remain the top cause of death in adults younger than age 45, followed by suicide, and homicide.[2]

As with other endemic diseases, successful treatment of trauma extends well beyond the boundaries of an individual hospital. Community-based prevention has included efforts to incorporate airbags in motor vehicles, mandate the use of helmets on motorcycles, encourage citizens to wear seat belts, punish intoxicated drivers, and promote responsible handgun ownership. All these measures have had an impact on the demographics of injury in much the same manner that smoking cessation, dietary modification, and routine mammography have affected the incidence of heart disease and cancer. When prevention fails, outcomes after injury are heavily influenced by the community's commitment to an organized system of trauma care.

MODERN TRAUMA SYSTEMS AND REGIONALIZATION

Following the landmark National Academy of Sciences report "Accidental Death and Disability: The Neglected Disease of Modern Society" in 1966,[4] a framework for trauma systems was developed by the American College of Surgeons (ACS) Committee on Trauma.[5,6] Comprised of governmentally designated or internally validated trauma centers, trauma systems represent a coordinated, organized, and patient-centric approach to the care of the injured patient.[7] A distinction between trauma center designation and verification is made to identify the types of resources available and the number of patients treated annually. Trauma center designation is a process outlined and developed at a state or local level. Trauma center verification is an evaluation process done by the ACS to evaluate and improve trauma care; the verification process is voluntary and identifies the presence of resources considered essential for the optimal care of the injured patient.[8] Trauma center levels range from Level I (a comprehensive regional resource providing 24-hour in-house coverage, referral resource for communities in nearby regions, leadership in prevention, research, and more) to Level V (basic emergency department [ED] facilities to implement advanced trauma life support [ATLS], after-hours activation protocols, limited surgery and critical care). Level I and Level II centers represent tertiary care centers; the standards for the provision of clinical care to injured patients for Level I and Level II trauma centers are identical. A trauma system is an example of tiered regionalization because the most seriously injured patients in a geographical catchment area are cared for at designated tertiary care trauma centers.[7] Over the past three decades, many studies have demonstrated significantly improved mortality,[9-15] morbidity,[16,17] and cost savings[17,18] after establishment of regionalized trauma systems.

THE ROLE OF THE ANESTHESIOLOGIST

At all levels of trauma care, anesthesiologists are uniquely juxtaposed with the multidisciplinary trauma team, serving both an administrative role in preparing the operating room (OR) and allocating resources for resuscitation, while providing direct patient care through definitive airway management and advanced resuscitation where appropriate.[19] Anesthesiologists also play a significant role as intensivists and pain management experts. Trauma patients represent a significant proportion of all OR cases handled during night and weekend shifts.[20] Regrettably, very few anesthesiologists in the United States consider trauma their primary specialty. This is distinct from European practice, where anesthesiologists frequently are found working in the prehospital environment, as an ED director, or as leader of a trauma team. The United States model, in which all anesthesiologists treat trauma patients—but few do so exclusively—has led to a relative dearth of research, publication, and education in this field.[20,21] This situation is unfortunate because trauma is a rapidly evolving field of study that presents unique challenges to the clinician and one in which improvements in care can have a dramatic impact on society as a whole.

Anesthesia for trauma patients is different from routine OR practice. Most urgent cases occur during off-hours, when the most experienced OR and anesthesia personnel may not be available. In small hospitals and military and humanitarian practice, austere conditions may influence the resources available. Patient information may be limited, and allergies, genetic abnormalities, and previous surgeries may create sudden crises. Patients are frequently intoxicated, with full stomachs and the potential for cervical spine instability. Simple operations may become complicated, and specialty surgical and anesthesia equipment may be required on short notice. Patients often have multiple injuries requiring complex positioning, multiple procedures, and the need to consider priorities in management. Occult injuries, such as tension pneumothorax, can manifest at unexpected times. Fortunately, there does not appear to be a higher risk for medical liability associated with the provision of anesthesia for trauma versus nontrauma surgical anesthesia cases.[22] Successful perioperative care of these patients requires a good understanding of the basics, supplemented by preparation, flexibility, and the ability to react quickly to changing circumstances.

This chapter provides an overview of important areas of trauma care for the anesthesiologist beginning with a description of the initial approach to an injured patient, followed by discussions of emergency airway management, resuscitation, and care of patients with central nervous system (CNS) injuries. The needs of orthopedic and reconstructive surgery patients are outlined and the chapter concludes with a discussion of postoperative issues for the anesthesiologist managing the trauma patient.

Prioritizing Trauma Care

PREHOSPITAL TRIAGE

Prehospital triage of the seriously injured trauma patient begins in the field, and is fraught with difficulty. Estimations of blood loss are imprecise and classically taught shock classifications are commonly confounded by extremes of age and variations in physiological reserve.[23] In 2011, the Centers for Disease Control and Prevention along with the National Highway Traffic Safety Administration collaborated with the ACS Committee on Trauma to revise previous field triage decision schemes in order to reduce over triage of patients with non–life-threatening injuries, and to help direct patients in most need of lifesaving interventions to appropriate trauma centers.[24] Current guidelines recommend a four-step assessment to assist prehospital providers with making decisions about which patients are most in need of transport to a trauma center (Box 66.1).

BOX 66.1 Four Steps for Assessing Need for Trauma Center Referral

Physiological Considerations

Systolic blood pressure <90 mm Hg
Glasgow Coma Scale ≤13
Respiratory rate <10 or >29 (or need for ventilatory support)

Anatomical Considerations

Any penetrating injury to the head, neck, torso, and extremities (proximal to the elbow or knee)
Chest wall instability/deformity
Amputation proximal to the wrist or ankle
Pelvic fracture
Open/depressed skull fracture
Paralysis

Mechanisms of Injury

Death of occupant in same vehicle
Fall from >20 feet
Extrication time >20 min

Special Patient or System Considerations

Age >55 years
Children
Patients on anticoagulants or with bleeding disorders
Burns (to be triaged to designated burn centers)
Pregnancy >20 weeks

Traditionally, mechanism of injury has been referred to as blunt versus penetrating trauma, with no further delineation as to how much energy was imparted, or information regarding anatomical and physiological insults. Some studies have suggested that mechanism of injury alone is a poor predictor for trauma center referral.[25,26] Others have demonstrated that distinct mechanisms, such as ejection from a vehicle or prolonged extrication time, clearly warrant trauma team activation.[27,28] In a study by Lerner and associates, the ACS Field Triage Decision scheme was examined, and interviews conducted with emergency medical technicians who transported patients to trauma centers based on mechanism alone.[29] Only three mechanisms of injury reliably predicted the need for referral to a trauma center when patients did not meet anatomical or physiological injury criteria: death of an occupant in the vehicle, fall greater than 20 feet, and extrication time greater than 20 minutes. Additional studies have justified mechanism of injury as a parameter that helps reduce inappropriate transport of patients with major trauma to nontrauma centers.[30,31] For more information on this subject see Chapter 67.

BLUNT VERSUS PENETRATING TRAUMA

Blunt and penetrating injuries are regularly disparate in presentation but may share similarities in terms of extent of injury.[19] Penetrating injuries are identified as ballistic and nonballistic. The point of injury in the patient with penetrating trauma may be utterly discernible—even to the inexpert provider—but the extent of tissue damage and depth of shock may be less detectible compared to the patient suffering from a blunt traumatic injury. Conversely, the patient with penetrating trauma will lose blood volume externally together with loss into body cavities, whereas the patient with blunt trauma may present in hemorrhagic shock with no obvious signs of hemorrhage. Multiple blunt traumatic insults, bleeding into compartments (e.g., unstable long-bone fractures), retroperitoneal hemorrhage (e.g., pelvic fractures, major vascular injury, solid organ damage), and bleeding into other body cavities may present as indolent hemorrhagic shock.[32]

ADVANCED TRAUMA LIFE SUPPORT

The performance of a thorough patient assessment, application of rapid diagnostic tests, and early activation of resources is vital for ensuring optimal outcomes in patients with severe traumatic injuries.[19] The ATLS course of the ACS is the most widely recognized training program for trauma physicians of all disciplines.[33] Although not comprehensive in subspecialty areas, the ATLS curriculum provides a framework and a common language for the care of injured patients. ATLS is based on a "primary survey" that includes simultaneous efforts to identify and treat life- and limb-threatening injuries, beginning with the most immediate. This focus on urgent problems first is captured by the "golden hour" catchphrase and is the most important lesson of ATLS. Resolution of urgent needs is followed by a meticulous secondary survey and further diagnostic studies designed to reduce the incidence of missed injuries. Knowing the basics of ATLS is essential for *any* physician who interacts with trauma patients. Fig. 66.1 is a simplified representation of the ATLS protocol.

ATLS emphasizes the "ABCDE" mnemonic: airway, breathing, circulation, disability, and exposure. Verification of an open airway and acceptable respiratory mechanics is of primary importance because hypoxia is the most immediate threat to life. Inability to oxygenate the patient will lead to permanent brain injury and death within 5 to 10 minutes. Trauma patients are at risk for airway obstruction and inadequate respiration for the reasons listed in Box 66.2. Endotracheal intubation, whether performed in the prehospital environment or in the ED,

BOX 66.2 Causes of Obstructed Airway or Inadequate Ventilation in a Trauma Patient

Airway Obstruction

Direct injury to the face, mandible, or neck
Hemorrhage in the nasopharynx, sinuses, mouth, or upper airway
Diminished consciousness secondary to traumatic brain injury, intoxication, or analgesic medications
Aspiration of gastric contents, blood, or a foreign body (i.e., dentures, broken teeth, soft tissue)
Misapplication of oral airway or endotracheal tube (esophageal intubation)

Inadequate Ventilation

Diminished respiratory drive secondary to traumatic brain or high cervical spine injury, shock, intoxication, hypothermia, or oversedation
Direct injury to the trachea or bronchi
Pneumothorax or hemothorax
Chest wall injury
Aspiration
Pulmonary contusion
Cervical spine injury
Bronchospasm secondary to smoke or toxic gas inhalation

BOX 66.3 Signs and Symptoms of Shock

Pallor
Diaphoresis
Agitation or obtundation
Hypotension
Tachycardia
Prolonged capillary refill
Diminished urine output
Narrowed pulse pressure

TABLE 66.1 Diagnostic and Therapeutic Options for Management of Traumatic Hemorrhage

Site of Bleeding	Diagnostic Modalities	Treatment Options

Outside the body	Physical examination	Direct pressure Surgical ligation

CT, Computed tomography; *FAST,* focused assessment by sonography for trauma.

must be confirmed immediately by capnometry. Esophageal intubation or endotracheal tube (ETT) dislodgement are common and devastating if not promptly corrected. Patients in cardiac arrest may have very low end-tidal carbon dioxide (CO_2) values; direct laryngoscopy should be performed if there is any question about the location of the ETT (see also Chapter 44).

If establishment of a secure airway and adequate ventilation requires a surgical procedure such as a tracheostomy, tube thoracostomy, or open thoracotomy, this procedure must precede all others. Indeed, these procedures are commonly performed in the ED, often before the arrival of an anesthesiologist. Subsequent surgery to convert a cricothyroidotomy to a tracheostomy or close an emergency thoracotomy may then follow in the OR.

Hemorrhage is the next most pressing concern since ongoing blood loss is inevitably fatal. The symptoms of shock are presented in Box 66.3. Shock is presumed to result from hemorrhage until proven otherwise. Assessment of the circulation consists of an early phase, during active hemorrhage, and a late phase, which begins when hemostasis is achieved and continues until normal physiology is restored. In the early phase, diagnostic efforts focus on the five sites of bleeding detailed in Table 66.1, the only areas in which exsanguinating hemorrhage can occur. Immediate actions to control hemorrhage can include application of pelvic binders for bleeding associated with pelvic fractures or tourniquet application for extremity injuries. Any surgical procedure to diagnose or control active hemorrhage is an emergency case that must be brought to the OR as soon as possible. This includes exploration of the neck or pericardium to rule out hemorrhage in sensitive compartments. In the OR, the trauma surgeon focuses on anatomic control of hemorrhage, whereas the anesthesiologist is responsible for restoring the patient's physiology. Goals for early and late resuscitation are discussed in more detail later.

After management of the circulation follows the assessment of the patient's neurologic status by calculation of the Glasgow Coma Scale (GCS) score (Box 66.4)[34]; examination of the pupils for size, reactivity, and symmetry; and determination of sensation and motor function in each of the extremities. Significant abnormalities on the neurologic examination are an indication for immediate cranial computed tomography (CT) scan. Most trauma patients with a diminished GCS score will have nonoperative conditions, but for the few who require operative evacuation of an epidural or subdural hematoma, timeliness of treatment has a strong influence on outcome. Patients with unstable spinal canal injuries and incomplete neurologic deficits will also benefit from early surgical decompression and stabilization.

The final step in the primary survey is complete exposure of the patient and a head-to-toe search for visible injuries or deformities, including deformities of bones or joints, soft tissue bruising, and any breaks in the skin. The anesthesiologist can assist in this procedure by support of the head and neck, maintenance of the airway, and care in manipulating the spine.

After the primary survey, a more deliberate secondary examination is undertaken that includes a thorough history and physical examination, diagnostic studies, and subspecialty consultation. Any remaining injuries are diagnosed at this time and treatment plans established. Indications for urgent or emergency surgery may also arise during the secondary survey. The presence of a limb-threatening injury due to vascular compromise, compartment syndrome, or a severely comminuted fracture is one such indication. Although the ABCDE issues must be addressed first, a pulseless extremity, compartment syndrome, near-amputation, or massively fractured extremity must go to the OR as soon as the patient is otherwise stable.

BOX 66.4 Glasgow Coma Score

Eye-Opening Response

4 = Spontaneous
3 = To speech
2 = To pain
1 = None

Verbal Response

5 = Oriented to name
4 = Confused
3 = Inappropriate speech
2 = Incomprehensible sounds
1 = None

Motor Response

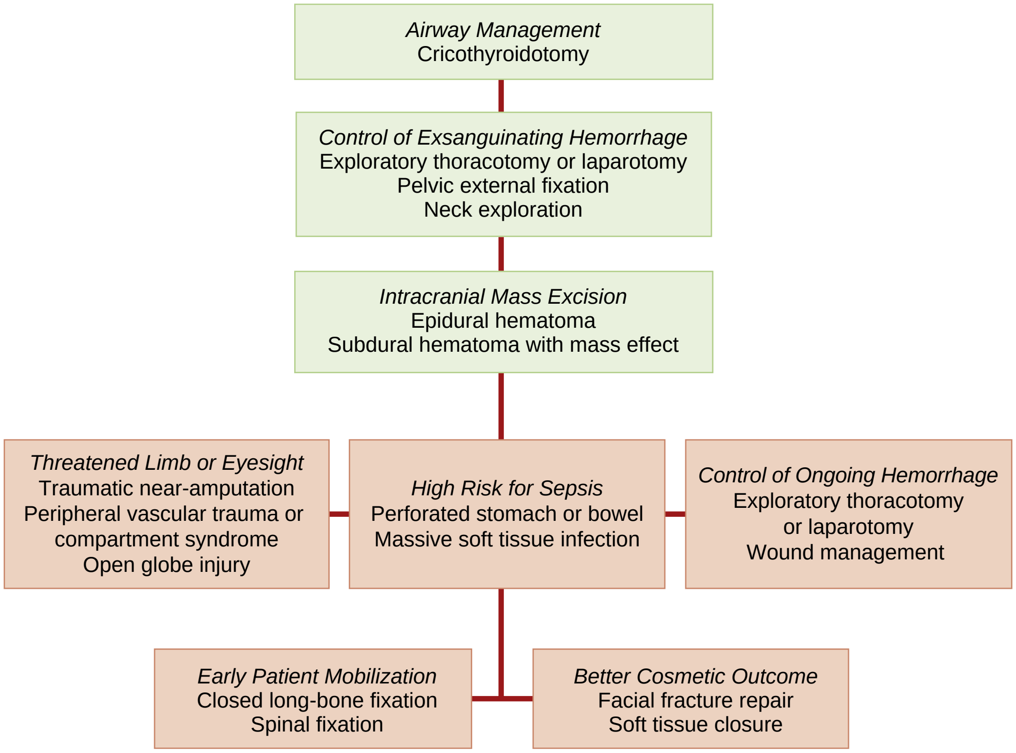
6 = Follows commands
5 = Localizes to painful stimuli
4 = Withdraws from painful stimuli
3 = Abnormal flexion (decorticate posturing)
2 = Abnormal extension (decerebrate posturing)
1 = None

The Glasgow Coma Score is the sum of the best scores in each of three categories.

INJURY PATTERNS PROMPTING URGENT OPERATIVE INTERVENTION

Fig. 66.2, an algorithm for prioritizing surgical management in trauma patients, is presented with the understanding that individual situations will vary according to available resources and the patient's response to therapy. A trauma patient will often arrive at the OR with the need for more than one surgical procedure by more than one surgical service. A trauma patient may have injuries requiring emergency surgery coexisting with injuries that can be repaired at any time. The anesthesiologist plays an important role in determining which procedures to perform, in which order, and which procedures should be postponed until the patient is more stable.

In selected cases with obvious, imminent exsanguination, patients should be directly admitted to the OR, bypassing the ED and radiology suite. Historically, it has been shown that up to a third of preventable trauma deaths may be caused by delays getting to the OR; in one registry study, mortality was increased by 1% for every 3 minutes of delay to laparotomy among hypotensive patients with abdominal injuries.[35-37] Steele and associates were among the first to describe a “direct to the OR” approach in San Diego, reporting data gathered over a 10-year period.[38] Patients with traumatic cardiac arrest, systolic blood pressure persistently lower than 100 mm Hg, amputation, or uncontrolled external hemorrhage were admitted directly to the OR for resuscitation, regardless of mechanism of injury. These triage criteria had poor sensitivity (24.1%) but high specificity (98%) in identifying patients truly in need of immediate surgery. Observed compared to predicted survival was significantly higher for the “direct to the OR”



Airway Management
Cricothyroidotomy
Control of Exsanguinating Hemorrhage
Exploratory thoracotomy or laparotomy
Pelvic external fixation
Neck exploration
Intracranial Mass Excision
Epidural hematoma
Subdural hematoma with mass effect
Threatened Limb or Eyesight
Traumatic near-amputation
Peripheral vascular trauma or compartment syndrome
Open globe injury
High Risk for Sepsis
Perforated stomach or bowel
Massive soft tissue infection
Control of Ongoing Hemorrhage
Exploratory thoracotomy or laparotomy
Wound management
Early Patient Mobilization
Closed long-bone fixation
Spinal fixation
Better Cosmetic Outcome
Facial fracture repair
Soft tissue closure

approach in this observational study. Similarly, Martin and associates reviewed their 10-year data from 2000 to 2009 for direct OR admission of 1407 patients (5% of all admissions) based on an expanded set of criteria including specific mechanisms.[39] After excluding patients who died on arrival (8%), 3.6% died in the OR and overall observed (5%) mortality was significantly lower than predicted (10%). Emergent surgical procedures were started within 30 minutes of arrival in 77% of patients and within 60 minutes in 92%.

Anesthesia in War and Austere Conditions

"While it is evident that the general principles of anesthesia are not affected by the circumstances of war, it is equally evident that it is our duty to assiduously seek those means in anesthesia which are especially suited to the exigencies of battle."[40]

Although written in 1942, these words are still true today, and many of the principles developed from earlier wars still apply on the modern battlefield or in a large-scale disaster (see also Chapter 68). Recent conflicts and events have allowed anesthesiologists, nurse anesthetists, and other providers to help improve management of traumatically injured patients in the areas of anesthesia, resuscitation, and damage control surgery. Management of battlefield casualties typically follows the same flow as outlined earlier, but with special consideration in the areas of prehospital interventions, resuscitation, technologic and logistic support, patient movement, mass casualty management, and surgical interventions.[41] Pain management considerations may also be affected by the nature of the injuries and transport considerations.[42]

Modern advancements in battle armor, prehospital interventions, provision of forward surgical support, and resuscitative strategies have had an impact on survival from combat injuries.[43] During the most recent conflicts in Iraq and Afghanistan, the killed-in-action rate decreased to 13.9% from 20.2% in Vietnam and World War II.[44] This is mirrored by a similar reduction in the case fatality rate. Paradoxically, the ability to get many of the severely wounded patients to a hospital (e.g., rapidly by helicopter) has led to an increase in the "died-of-wounds" rate. Most likely this rate would be even higher if not for improvements in surgical management such as damage control techniques, improved intensive care unit (ICU) care, evolving resuscitation strategies, tactical combat casualty care initiatives, and institution of a theater-wide trauma system approach.[45] More recently, transition from a 2-hour to an aggressive 1-hour target for definitive care for combat casualties has also contributed to a reduction in case fatality and killed-in-action rates.[46]

One of the major advances in battlefield medical support has been the rapid movement of patients out of the theater of operations to more comprehensive medical facilities. Even in the late 1960s, wounded soldiers were evacuated out of Vietnam within 3 days of injury. In the most recent conflict, the time from injury in the Middle East until movement to more definitive medical care in Europe or North America is often within 24 to 48 hours.[47] This may include initial in-theater damage control surgery followed by one or two aeromedical evacuation missions lasting up to 12 hours with a critical care air transport team (CCATT). In preparation for such rapid movement, the anesthesiologist must ensure that perioperative interventions such as airway management, pain control, and adequacy of resuscitation are addressed before transfer. In addition, anesthesiologists are frequently assigned to a CCATT as the physician team member based on their overall skill set and ability to provide support en route to critically ill or injured patients. Beyond the support provided during wartime, the CCATT also has proved useful for the movement of critical patients during large-scale disasters such as occurred after Hurricane Katrina in 2005.[48]

Mass casualty situations are common in wartime conditions, although the role of the anesthesiologist will vary depending on the number of patients and requirements for urgent surgical interventions. Given the limited number of anesthesia providers in most combat-related scenarios, often they are not involved in the triage process. If available, however, anesthesia support can enhance emergency airway management, establishment of venous access, and supervision of resuscitative efforts. Only 10% to 20% of arriving casualties require immediate lifesaving interventions, although a much larger percentage will ultimately require surgical procedures.[49] A well-developed trauma system is persistently evolving, and management of mass casualty scenarios will become routine.[50]

Overall, anesthetic management of battlefield casualties is similar to that for patients in a civilian trauma setting; however, many factors must be considered in the perioperative plan for a combat casualty.[51] Environmental considerations such as extremes of temperature, availability of water, contamination with sand, lack of consistent electricity, and other aspects may have to be taken into consideration. Logistic support chains may be long and unable to provide sufficient supplies in the early phases of a conflict. Deployable equipment, such as drawover vaporizer systems or portable anesthesia systems, may be different from those used during peacetime, so predeployment training is vital (Fig. 66.3).[52] In addition, techniques such as total intravenous anesthesia and regional anesthesia or analgesia may be better options making familiarity with their management and associated equipment an imperative (see also Chapter 46).[53]

Optimal care of wartime casualties or victims of large disasters requires not only knowledge of a broad range of anesthetic principles and techniques but also the ability to be flexible in the face of a rapidly changing environment. With special training in airway management, provision of anesthesia and sedation, resuscitation, and pain management, anesthesiologists may find themselves involved in triage, emergency management, and perioperative and critical care.

Emergency Airway Management

The American Society of Anesthesiologists (ASA) algorithm for management of difficult airways (see also Fig. 44.1) modified for trauma is a useful starting point for the trauma anesthesiologist, whether in the ED or the OR (see also Chapter 44).[54] The concept of the algorithm is an important one. The anesthesiologist should have a plan for the initial approach to the airway and for coping with any difficulties that might develop. Fig. 66.4 is a typical algorithm for emergency

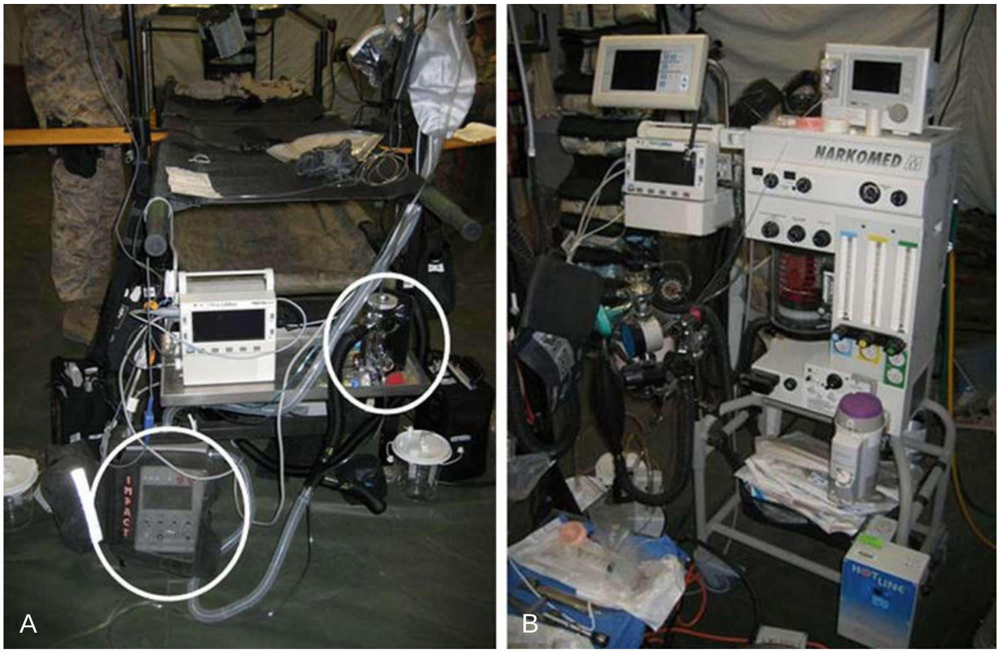

Fig. 66.3 Deployable military anesthesia equipment. (A) Drawover vaporizer and portable ventilator *(circled)* in field hospital. (B) Portable anesthesia machine. (Used with permission from CPT Bruce Baker, MD, USN.)

intubation of an unstable trauma patient. Note that it differs from the ASA algorithm in that reawakening the patient is seldom an option because the need for emergency airway control will presumably remain. Once the decision to obtain a definitive airway is made, efforts will continue until a cuffed tube is in position in the trachea, whether by conventional intubation or via a surgical approach. Failure to commit to a surgical airway soon enough results in bad outcomes more commonly than do complications of a procedure that might have been unnecessary.

INDICATIONS

The goal of emergency airway management is to ensure adequate oxygenation and ventilation while protecting the patient from the risks for aspiration. Endotracheal intubation is commonly required and is specifically indicated in the following conditions:

- Cardiac or respiratory arrest
- Respiratory insufficiency (see Box 66.2)
- Airway protection
- Need for deep sedation or analgesia, up to and including general anesthesia
- Ventilation management of patients with space-occupying intracranial lesions and evidence of increased intracranial pressure (ICP)
- Delivery of a 100% fraction of inspired oxygen (FiO_2) to patients with carbon monoxide poisoning
- Facilitation of the diagnostic workup in uncooperative or intoxicated patients

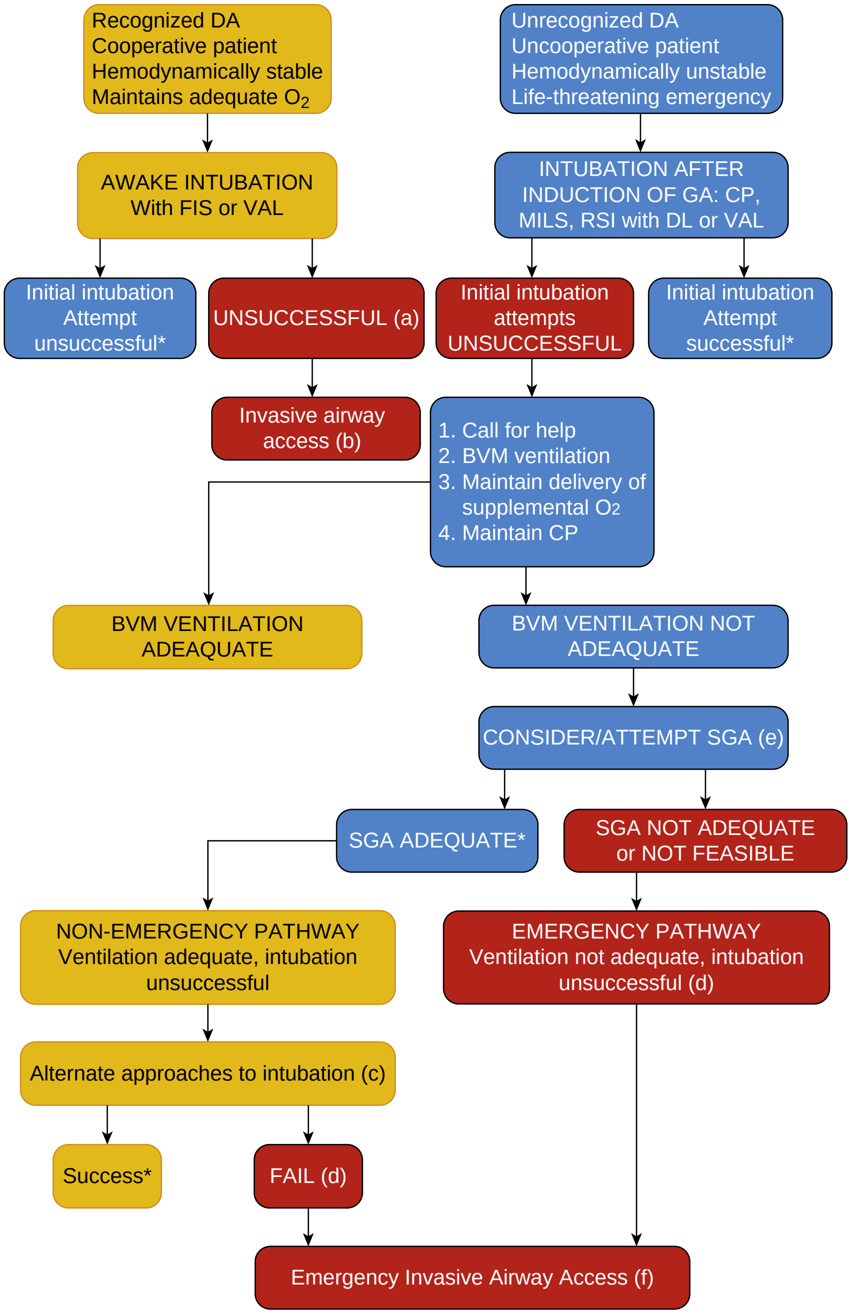
APPROACH TO ENDOTRACHEAL INTUBATION

In general, monitoring standards for airway management should be the same in the ED and OR, including an electrocardiogram (ECG), blood pressure, oximetry, and capnometry. Appropriate equipment, including an oxygen source, bag-valve-mask ventilating system, mechanical ventilator, suction, and a selection of laryngoscope blades (including video laryngoscope), ETTs, and devices for managing difficult tracheal intubations, should be available in any location where emergency intubation is likely, including the ED.

Endotracheal intubation is best accomplished in almost all cases with a modified rapid sequence approach by an experienced clinician. Although concern may exist that the use of neuromuscular blocking drugs and potent anesthetics outside the OR will be associated with a more frequent complication rate, in fact the opposite is more likely correct. Anesthesia and neuromuscular blockade allow the best tracheal intubating conditions on the first approach to the airway, which is advantageous in an uncooperative, hypoxic, or aspirating patient. Attempts to secure the airway in an awake or lightly sedated patient increase the risk for airway trauma, pain, aspiration, hypertension, laryngospasm, and combative behavior. Experienced providers, supported by appropriate monitoring and equipment, have achieved results of medication-assisted intubation outside the OR that are equivalent to those for emergency tracheal intubation within the OR.[55-57]

PROPHYLAXIS AGAINST PULMONARY ASPIRATION OF GASTRIC CONTENTS

A trauma patient should always be treated as having a full stomach and at risk for aspiration of gastric contents during induction of anesthesia (see also Chapter 44). Reasons include ingestion of food or liquids before the injury, swallowed blood from oral or nasal injuries, delayed gastric emptying associated with the stress of trauma, and administration of liquid contrast medium for abdominal CT scanning.



Recognized DA
Cooperative patient
Hemodynamically stable
Maintains adequate O2
Unrecognized DA
Uncooperative patient
Hemodynamically unstable
Life-threatening emergency
AWAKE INTUBATION With FIS or VAL
INTUBATION AFTER INDUCTION OF GA: CP, MILS, RSI with DL or VAL
Initial intubation Attempt unsuccessful*
UNSUCCESSFUL (a)
Initial intubation attempts UNSUCCESSFUL
Initial intubation Attempt successful*
Invasive airway access (b)

2. BVM ventilation
3. Maintain delivery of supplemental O2
4. Maintain CP
BVM VENTILATION ADEQUATE
BVM VENTILATION NOT ADEQUATE
CONSIDER/ATTEMPT SGA (e)
SGA ADEQUATE*
SGA NOT ADEQUATE or NOT FEASIBLE
NON-EMERGENCY PATHWAY Ventilation adequate, intubation unsuccessful
EMERGENCY PATHWAY Ventilation not adequate, intubation unsuccessful (d)
Alternate approaches to intubation (c)
Success*
FAIL (d)
Emergency Invasive Airway Access (f)

* Confirm ventilation, tracheal intubation or SGA placement with standard confirmatory techniques (exhaled CO_2, misting of tube, auscultation of breath sounds, improving SpO_2). If perfusion (and exhaled CO_2) absent, use additional confirmation methods (e.g., repeat laryngoscopy, bronchoscopy, esophageal detector device, chest X-ray).

(a) Other options in ASA algorithm:
- Ventilation with a face mask or SGA might be difficult or impossible in a patient with maxillofacial trauma
- Local anesthesia infiltration or regional nerve blockade are of limited value in extensive trauma surgery.

(b) Invasive airway access includes surgical or percutaneous cricothyrotomy or tracheostomy, transtracheal jet ventilation and retrograde intubation.

(c) Alternative difficult intubation approaches include (but are not limited to): VAL, SGA (e.g., laryngeal mask airway [LMA] as an intubation conduit with or without flexible scope guidance), flexible scope intubation (FSI), intubating stylet or tube changer, and light wand. Blind intubation (oral or nasal) is discouraged in patients with maxillofacial trauma and laryngeal or tracheal injury.

(d) Aborting the case and awakening the patient to optimize and re-attempt intubation via a different airway technique (e.g., awake intubation) is impractical in most trauma cases due to the emergent condition of the patient.

(e) Emergency non-invasive airway ventilation consists of SGA.

(f) Surgical airway kit should be immediately available.

Fig. 66.4 Emergency airway management algorithm in trauma. Individual practitioners and trauma hospitals should determine their own algorithm, based on available skills and resources. *ASA,* American Society of Anesthesiologists; *BVM,* bag-valve-mask; *CP,* cricoid pressure; *DA,* difficult airway; *DL,* direct laryngoscopy; *FIS,* flexible intubation scope; *GA,* general anesthesia; *MILS,* manual in-line stabilization; *RSI,* rapid sequence intubation; *SGA,* supraglottic airway; *VAL,* video-assisted laryngoscopy. (Modified from Hagberg CA, Kaslow O. Difficult airway management algorithm in trauma updated by COTEP. *ASA Newsletter.* 2014;78:56–60.)

Cricoid pressure—the Sellick maneuver—has been recommended to be applied continuously during emergency airway management from the time the patient loses protective airway reflexes until ETT placement and cuff inflation are confirmed. The Sellick maneuver consists of elevating the patient's chin (without displacing the cervical spine) and then pushing the cricoid cartilage posteriorly to close the esophagus. However, cricoid pressure may worsen the laryngoscopic grade of view in up to 30% of patients[58] without providing effective prevention of aspiration of gastric contents.[59] In a prehospital study evaluating the impact of cricoid pressure on subsequent intubation success, discontinuing cricoid pressure usually facilitated intubation of the trachea without worsening the grade of laryngoscopic view.[60] Thus cricoid pressure should be released in the trauma patient if likely to facilitate intubation attempts. The lack of evidence supporting the use of cricoid pressure and its potential to make intubation more difficult led the American Heart Association to recommend discontinuation of its use during cardiac arrest situations.[61] Additionally, the Eastern Association for the Surgery of Trauma Practice Management Guidelines for emergency tracheal intubation have removed it as a class 1 recommendation.[62]

In the traditionally defined rapid sequence induction of anesthesia, any attempt at ventilation between administration of medication and intubation is avoided, presumably because positive-pressure ventilation may force gas into the patient's stomach, leading to regurgitation and aspiration. Sellick's original paper described ventilation during cricoid pressure in patients with full stomachs with the belief that cricoid pressure during mask ventilation would prevent gastric inflation.[63] Although this may be true, cricoid pressure reduces tidal volumes, increases peak inspiratory pressure, or prevents ventilation.[64] On the other hand, the increase in oxygen consumption in trauma patients necessitates preoxygenation whenever possible. If preoxygenation is not possible because of facial trauma, decreased respiratory effort, or agitation, rapid desaturation is a possibility. Positive-pressure ventilation during all phases of induction provides the largest possible oxygen reserve during emergency airway management and will help mitigate hypoxia if intubation proves difficult. In this situation, large tidal volumes and high peak inspiratory pressures should be avoided. Application of cricoid pressure during attempts at positive-pressure ventilation should be considered to reduce gastric inflation, but it may prevent effective ventilation in some patients necessitating discontinuation.

PROTECTION OF THE CERVICAL SPINE

Standard practice dictates that all victims of blunt trauma be assumed to have an unstable cervical spine until this condition is ruled out. The airway management of these patients receives much attention from anesthesiologists because direct laryngoscopy causes cervical motion, with the theoretical potential to exacerbate spinal cord injury (SCI). Stabilization of the cervical spine will generally occur in the prehospital environment, with the patient already having a rigid cervical collar in place. This collar may be kept in place for several days before the complete gamut of tests to rule out cervical spine instability have been completed (see later discussion). The presence of an "uncleared" cervical spine mandates the use of manual in-line stabilization without application of traction throughout any attempt at intubation.[33] This approach allows removal of the front of the cervical collar to facilitate wider mouth opening and jaw displacement; however, this may slightly lengthen the time to intubation and worsen laryngeal visualization during laryngoscopy compared to intubation attempts without manual in-line stablilization.[65] Manual in-line stabilization has been tested through considerable clinical experience and is the standard of care in the ATLS curriculum. Emergency awake fiberoptic intubation, though requiring less manipulation of the neck, is generally very difficult because of airway secretions and hemorrhage, rapid desaturation, and lack of patient cooperation; and is best reserved for cooperative patients with known cervical instability under controlled conditions. Indirect video laryngoscopy offers the potential to enjoy the best of both worlds: an anesthetized patient and decreased cervical motion.[66,67] In comparative studies of direct laryngoscopy, video laryngoscopy, fiberoptic intubation, blind nasal intubation, or cricothyrotomy—in patients with known cervical cord or spine injuries, or both—there is no difference in neurologic deterioration with technique used, and no clear evidence that direct laryngoscopy worsens outcome.[68]

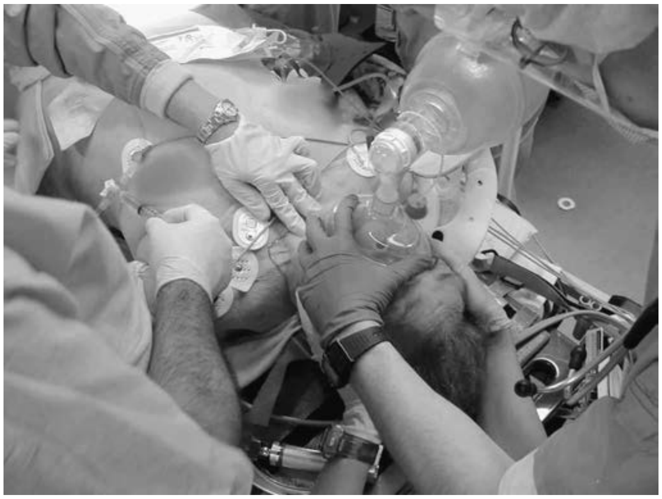

Fig. 66.5 Emergency intubation of a trauma patient immobilized on a long spine board. The front of the cervical collar is removed once in-line manual stabilization of the spine is established, allowing for cricoid pressure and greater excursion of the mandible. (Reprinted with permission from Dutton RP. Spinal cord injury. *Int Anesthesiol Clin.* 2002;40:111.)

PERSONNEL

Emergency endotracheal intubation requires more assistance than an intubation performed under controlled conditions (see also Chapter 6). Three providers are required to ventilate the patient and manage the airway, administer medications, and provide manual in-line stabilization (if indicated); a fourth provider may be needed to provide cricoid pressure if deemed appropriate. Fig. 66.5 is an illustration of this approach. Additional assistance may be required to restrain a patient who is combative because of intoxication or traumatic brain injury (TBI).

The immediate presence of a surgeon or other physician who can expeditiously perform a cricothyroidotomy is desirable. Even if a surgical airway is not required, additional experienced hands may prove useful during difficult intubations. The surgeon may also wish to inspect the upper airway during laryngoscopy or video laryngoscopy if trauma to the face or neck has occurred. Urgent tube thoracostomy may prove necessary in some trauma patients to treat a tension pneumothorax that develops with the onset of positive-pressure ventilation.

ANESTHETICS AND INDUCTION OF ANESTHESIA

Any intravenous anesthetic administered to a trauma patient in hemorrhagic shock may cause profound hypotension and even cardiac arrest because of inhibition of circulating catecholamines. Although propofol is the mainstay of intravenous induction in the OR, its use in trauma patients is problematic because of its vasodilatory and negative inotropic effects. Moreover, pharmacokinetic and pharmacodynamic studies in a swine hemorrhagic shock model suggest a significant reduction in propofol dosage of more than 80% to achieve the targeted effect site concentration.[69,70] Unfortunately, there is no corresponding clinical data on the impact of reduced propofol dosing in the setting of hemorrhagic shock on recall and awareness.

The most commonly used induction agent in the United States in the ED or trauma setting is etomidate.[71] Etomidate administered in a range of 0.2 to 0.3 mg/kg is associated with hemodynamic stability and has an onset/duration profile like that of succinylcholine. Its safety for use in rapid sequence induction in trauma patients has been challenged although these studies are largely retrospective with the potential for selection bias and other methodologic deficiencies.[72,73] Although etomidate is associated with transient adrenal cortical suppression after a single dose, this appears not to be clinically significant when a single dose is used for induction for intubation in both trauma and mixed surgical-medical patients undergoing rapid sequence induction.[74-76] Etomidate can cause myoclonic jerks during its onset, but use of a rapidly acting neuromuscular blocking agent, such as succinylcholine, mitigates this effect substantially.

Ketamine is also a frequently used induction agent for hypotensive trauma patients due to its centrally mediated increase in sympathetic tone and catecholamine release.[77] Its use in patients with concomitant TBI has been questioned based on older reports of associated ICP elevation.[78] More recent analysis, however, suggests that the preservation of cerebral perfusion by maintenance of mean arterial blood pressure in hemodynamically unstable patients is more important than any theoretical risk to the brain caused by ketamine's tendency to increase cerebral activity and ICP.[78,79] Some investigators have also raised concern that the psychotropic effects associated with ketamine may increase the risk of acute- and posttraumatic stress disorders in trauma patients,[80,81] although this was not found in a study examining its intraoperative use in burn patients.[82] Of more concern is the potential for barriers to its use based on institutional dispensing, tracking, and documentation procedures preventing timely access to ketamine. When barriers exist limiting its availability, ketamine may not be as readily available in the emergency setting compared to other induction agents. Due to its abuse potential, consideration has been made to reclassify ketamine as a Schedule 1 drug, potentially placing further barriers to its availability.[83] Overall, ketamine continues to be a very commonly used drug for rapid sequence induction in the trauma patient.[71]

Hypotension will likely develop in patients with hypovolemia with the administration of any anesthetic because of interruption of compensatory sympathetic outflow and the sudden change to positive-pressure ventilation. Previously healthy young patients can lose up to 40% of their blood volume before hypotension occurs, thereby leading to potentially catastrophic circulatory collapse with induction of anesthesia, regardless of the anesthetic chosen. The dose of anesthetic must be decreased in the presence of hemorrhage, including no anesthetic at all in patients with life-threatening hypovolemia. Rapid sequence induction of anesthesia and endotracheal intubation may proceed with muscle relaxants alone, although onset time may be prolonged in a patient with circulatory impairment. Subsequent patient recall of intubation and emergency procedures is highly variable and affected by the presence of coexisting TBI, intoxication, and the depth of hemorrhagic shock (see also Chapter 9). Decreased cerebral perfusion inhibits memory formation but cannot be reliably associated with any particular blood pressure or chemical marker. Administration of 0.2 mg of scopolamine (a tertiary ammonium vagolytic) may inhibit memory formation in the absence of anesthetic drugs in this situation, but it may interfere with subsequent neurologic examination because of its long half-life. Small doses of midazolam will reduce the incidence of patient awareness but also can contribute to hypotension. Although recall of ED and OR events is not unusual in this circumstance, anesthesia provider liability appears to be limited; an analysis of intraoperative awareness lawsuits in the ASA Closed Claims Database revealed no claims related to surgery in trauma patients.[84]

NEUROMUSCULAR BLOCKING DRUGS

Succinylcholine remains the neuromuscular blocker with fastest onset—less than 1 minute—and shortest duration of action—5 to 10 minutes. These properties make it popular for rapid sequence induction of anesthesia. Although the use of succinylcholine may allow return of spontaneous respiration before the development of significant hypoxia in the "cannot intubate, cannot ventilate" situation, this is unlikely to be of benefit in an emergency intubation in a trauma patient. The anesthesiologist should not rely on return of spontaneous breathing in time to salvage a difficult airway management problem but should instead proceed with efforts to obtain a definitive airway, including cricothyroidotomy if other possibilities have been exhausted.

Administration of succinylcholine is associated with several adverse consequences. Increases in serum potassium of 0.5 to 1.0 mEq/L are expected, but in certain patients K^+ may increase by more than 5 mEq/L.[85] A hyperkalemic response is typically seen in burn victims and those with muscle pathology secondary to direct trauma, denervation (as with SCI), or immobilization. Hyperkalemia is not seen in the first 24 hours after these injuries, and succinylcholine may be used safely for acute airway management. Patients at risk are those with underlying pathologic processes before their traumatic event or those undergoing subsequent surgery in the weeks to months after injury.

Succinylcholine causes an increase in intraocular pressure and should be used cautiously in patients with ocular trauma.[86] Succinylcholine may also increase ICP,[87] making its use in patients with brain trauma controversial. In both these cases, however, hypoxia and hypercapnia may be as damaging as the transient increase in pressure caused by the drug. If the use of succinylcholine will lead to faster intubation, its benefits may outweigh its risks. The provider must weigh the use of succinylcholine in each individual situation based on acuity, anticipated speed with which intubation can be accomplished, and likelihood that hypoxia will develop.

Alternatives to succinylcholine include rocuronium 0.9 to 1.2 mg/kg and vecuronium 0.1 to 0.2 mg/kg. Rocuronium is preferred because it has a more rapid onset of action than that of vecuronium. With the availability of sugammadex, a rapid onset selective binding agent for rocuronium, rapid sequence induction and intubation with rocuronium followed by reversal with sugammadex allows for more rapid return of spontaneous ventilation than with succinylcholine.[88] Basically, the combination of rocuronium and sugammadex provides all the advantages of succinylcholine, but none of the complications.[89,90] Because these drugs have no significant cardiovascular toxicity, large doses can be administered to achieve rapid (1- to 2-minute) paralysis.

Specific situations will always exist in which maintaining spontaneous ventilation during intubation is the preferred way to proceed. If patients can maintain their airway temporarily but have clear indications for an artificial airway (e.g., penetrating trauma to the trachea), slow induction with ketamine or inhaled sevoflurane through cricoid pressure will enable placement of an ETT without compromising patient safety.

ADJUNCTS TO ENDOTRACHEAL INTUBATION

Equipment to facilitate difficult intubation should be readily available wherever emergency airway management is performed. The equipment available depends on the preferences of the anesthesiologist; the usefulness of most special equipment depends more on previous experience than on any intrinsic properties of the device. Certain items deserve mention, however, because they are frequently cited as aids to management of a difficult airway.

The gum elastic bougie, or intubating stylet, is an inexpensive and easily mastered adjunct for management of a difficult airway. The stylet is placed through the vocal cords via direct laryngoscopy, and the ETT is then advanced over the stylet into the trachea. Placement of the bougie is easier than direct placement of an ETT because of both its smaller diameter and the ability of an experienced operator to feel it enter the trachea even when the glottic opening cannot be visualized. The bougie is passed under the epiglottis and gently advanced; if resistance is met, the bougie is withdrawn, rotated slightly, and advanced again. In this fashion the anesthesiologist can blindly palpate the larynx until the bougie advances into the trachea. The bougie also can be used with direct and indirect video laryngoscopy systems and is especially useful in the ED when the sniffing position cannot be used because of uncertainty about the cervical spine.

Supraglottic airway (SGA) devices, such as the laryngeal mask airway (LMA) (LMA North America, San Diego, CA), are recommended in the ASA algorithm for management of a patient with a difficult airway. The LMA can be used as a guide for intubation when an unsuspected difficult intubation is encountered in a trauma patient; an ETT may be placed blindly through the lumen of the LMA and into the trachea, or a fiberoptic bronchoscope may be used to guide the tube through the LMA. The LMA is an appropriate rescue device for a difficult airway situation in trauma, provided no major anatomic injury or hemorrhage is present in the mouth and larynx. In our practice the LMA has most commonly been used as a bridge to emergency tracheostomy because it allows more controlled conditions than a cricothyroidotomy.

FACIAL AND PHARYNGEAL TRAUMA

Trauma to the face and upper airway poses difficulties for the anesthesiologist.[91] Serious skeletal derangements may be masked by apparently minor soft tissue damage. Failure to identify an injury to the face or neck can lead to acute airway obstruction secondary to swelling and hematoma. Laryngeal edema is also a risk in patients who have suffered chemical or thermal injury to the pharyngeal mucosa. Intraoral hemorrhage, pharyngeal erythema, and change in voice are all indications for early intubation.

In general, both maxillary and mandibular fractures will make ventilation by mask more difficult, whereas mandibular fractures will make endotracheal intubation easier. Palpation of the facial bones before manipulation of the airway will alert the anesthetist to these possibilities. Patients with injuries to the jaw and zygomatic arch often have trismus. Although the trismus will resolve with the administration of neuromuscular blocking agents, preinduction assessment of airway anatomy may be difficult. Bilateral mandibular fractures and pharyngeal hemorrhage may lead to upper airway obstruction, particularly in a supine patient, although intubation may be easier because of loss of skeletal resistance to direct laryngoscopy. A patient arriving at the ED in the sitting or prone position because of airway compromise is best left in that position until the moment of anesthetic induction and intubation.

THE FIELD PLACED AIRWAY

In many settings, prehospital providers work under protocols that allow for advanced airway management including intubation and placement of an SGA. It is recommended that the individuals responsible for airway management at the ED level be familiar with the protocols and devices available in their region to facilitate early assessment and airway exchange if indicated. All intubations done in the field should be immediately confirmed using capnometry. In the event of cardiac arrest and inability to confirm correct placement by observation of end-tidal CO_2, direct laryngoscopy or video laryngoscopy can be employed to visualize position of the ETT. When an SGA device is used in the prehospital setting, the positioning and ability to ventilate should be confirmed by capnometry, presence of breath sounds, and chest movement. If there is adequate ventilation, replacement of the SGA can be delayed during the initial evaluation.

Since the SGA is not considered a secured definitive airway, it should be changed out to a cuffed ETT as soon as practical. When faced with changing out an SGA, preparation is the key concept. Unfortunately, there is a paucity of literature discussing the technique of "changing out" an SGA with no single preferred method in the trauma patient. This procedure can be challenging with increased risk of losing the patient's airway. Prior to deciding which technique to use, it is extremely important to have a discussion with the prehospital care provider that managed the patient's airway in the field to determine the following information:

- What was the reason for placing an SGA?
- Were attempts at oral or nasal intubation made? How many?
- What laryngoscope/video laryngoscope was used?
- What anatomy was visualized during attempts?
- What, if any, medications were administered during the attempts?

The answers to these questions may suggest a difficult airway prompting more guarded management during the exchange process. The three options for exchange in the trauma setting are: (1) remove the SGA and replace under direct or video laryngoscopy, (2) use the SGA to place an ETT or exchange catheter, or (3) proceed to a surgical airway. The second option will largely be guided by the specific SGA, channel size, and available equipment.[92-94] Of note, there have been reports of pharyngeal, glottic, and lingual edema with the use of various SGA devices likely secondary to exaggerated anatomical distortion and indirect vascular compression.[93] It is unclear whether this is an anticipated finding in some patients with proper placement and inflation of the proximal oropharyngeal cuff or due to overinflation of the cuff. In the only published series of patients presenting with prehospital placement of the King LT (S)-D (King Systems; Noblesville, IN), 7 of 9 trauma patients ultimately underwent tracheostomy in the OR due to concerns for concomitant facial trauma, observed upper airway edema, or failed attempts at direct laryngoscopy.[93]

On occasion, prehospital personnel will perform a blind nasotracheal intubation in the spontaneously ventilating trauma patient. Successful exchange of this nasotracheal tube on arrival to the ED is consistently easier in comparison with the SGA. Nasotracheally placed tubes in the field are usually a result of the prehospital providers not being credentialed for drug-facilitated intubation. As a result, most of these patients have not had laryngoscopy performed and therefore are less likely to have airway edema from intubation attempts. Again, in this scenario, it is prudent to facilitate the intubation with muscle relaxation and adequate sedation/anesthesia prior to attempting laryngoscopy. A video laryngoscope is preferred as it allows for an expanded view of the glottis with visualization of the nasotracheal tube prior to removal of the nasal tube. Simple exchange under direct or video visualization with an oral ETT is usually all that is required. Once again, it cannot be overemphasized that a bougie be readily available in these situations for rapid placement into the glottis with various sized ETTs readily available. If one is unable to adequately visualize the glottis with laryngoscopy, it is recommended that the nasotracheal tube be left in place for a period to allow for either a controlled tracheostomy or swelling to improve and an exchange for an oral tube made later.

Resuscitation from Hemorrhagic Shock

Resuscitation refers to restoration of normal physiology after injury. Resuscitation from hemorrhagic shock refers specifically to restoration of normal circulating blood volume, normal vascular tone, and normal tissue perfusion. Resuscitation begins immediately after injury, via the patient's own compensatory mechanisms, and continues through the prehospital, ED, OR, and ICU phases of care.

PATHOPHYSIOLOGY OF HEMORRHAGIC SHOCK

During massive hemorrhage an imbalance occurs between systemic oxygen delivery and oxygen consumption. Blood loss leads to hemodynamic instability, coagulopathy, decreased oxygen delivery, decreased tissue perfusion, and cellular hypoxia. The initial response to hemorrhage takes place on the macrocirculatory level and is mediated by the neuroendocrine system. Decreased arterial blood pressure leads to vasoconstriction and release of catecholamines to preserve blood flow to the heart, kidney, and brain, whereas other regional beds are constricted. Pain, hemorrhage, and cortical perception of traumatic injuries lead to the release of hormones and other inflammatory mediators, including renin, angiotensin, vasopressin, antidiuretic hormone, growth hormone, glucagon, cortisol, epinephrine, and norepinephrine.[95] This response sets the stage for the microcirculatory response that follows.

Individual ischemic cells respond to hemorrhage by taking up interstitial fluid, thus further depleting intravascular fluid.[96] Cellular edema may choke off adjacent capillaries and result in the no-reflow phenomenon, which prevents reversal of ischemia even in the presence of adequate macroperfusion.[97] Ischemic cells produce lactate and free radicals, which accumulate in the circulation if perfusion is diminished. These compounds cause direct damage to the cell and form the bulk of the toxic load that washes back to the central circulation when flow is reestablished. Ischemic cells also produce and release inflammatory factors—prostacyclin, thromboxane, prostaglandins, leukotrienes, endothelin, complement, interleukins, tumor necrosis factor, and others.[98] Fig. 66.6 shows the generalized inflammatory response to shock, with an emphasis on immune system amplification. This inflammatory response, once begun, becomes a disease process independent of its origin. Such alterations lay the foundations for subsequent development of multiple organ failure, a systemic inflammatory process that leads to dysfunction of different vital organs and accounts for high mortality rates.[99]

Specific organ systems respond to traumatic shock in specific ways. The CNS is the prime trigger of the neuroendocrine response to shock, which maintains perfusion to the heart, kidney, and brain at the expense of other tissues.[100] Regional glucose uptake in the brain changes during shock.[101] Reflexes and cortical electrical activity are both depressed during hypotension; these changes are reversible with mild hypoperfusion but become permanent with prolonged ischemia. Failure to recover preinjury neurologic function is a marker for a poor prognosis, even when normal vital signs are restored.[102]

The *kidney* and *adrenal glands* are prime responders to the neuroendocrine changes associated with shock and produce renin, angiotensin, aldosterone, cortisol, erythropoietin, and catecholamines.[103] The kidney maintains glomerular filtration in the face of hypotension by selective vasoconstriction and concentration of blood flow in the medulla and deep cortical area. Prolonged hypotension leads to decreased cellular energy and an inability to concentrate urine (renal cell hibernation), followed by patchy cell death, tubular epithelial necrosis, and renal failure.[104]

The *heart* is preserved from ischemia during shock because of maintenance of or even an increase in nutrient blood flow, and cardiac function is well preserved until the late stages. Lactate, free radicals, and other humoral factors released by ischemic cells all act as negative inotropes and, in a bleeding patient, may produce cardiac dysfunction as the terminal event in the shock spiral.[105] A patient with cardiac disease or direct cardiac trauma is at great risk for

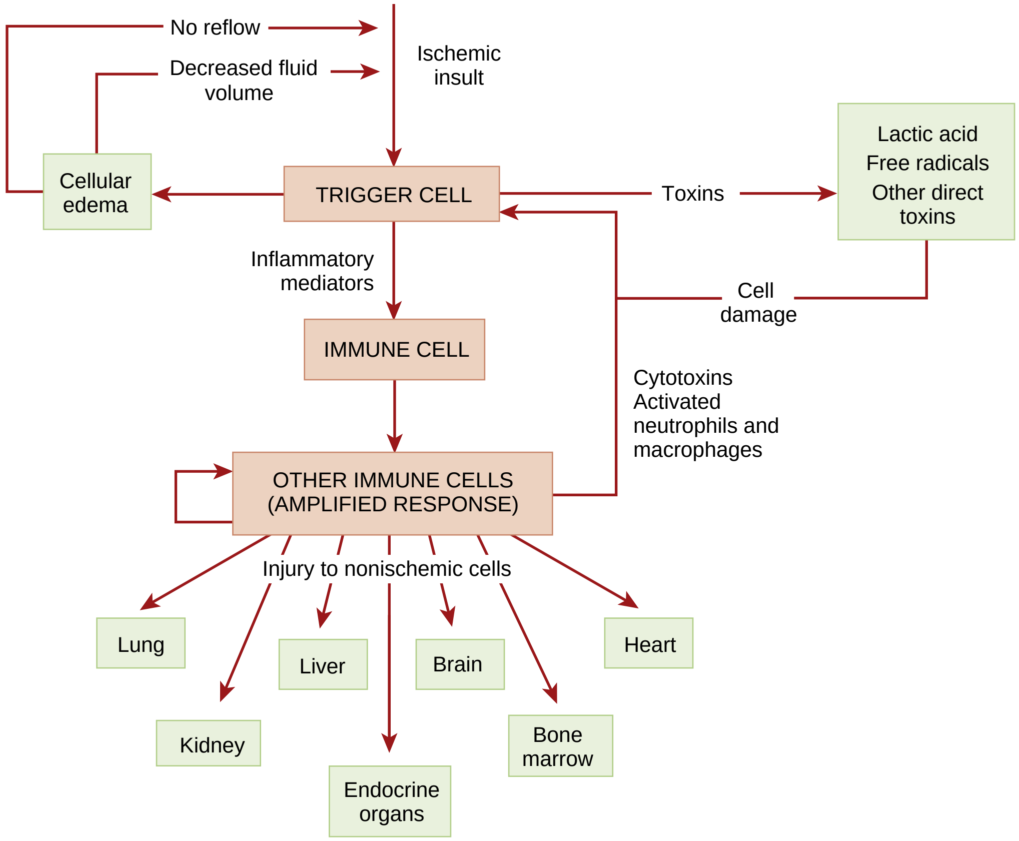

Fig. 66.6 The "shock cascade." Ischemia of any given region of the body will trigger an inflammatory response that will impact nonischemic organs even after adequate systemic perfusion has been restored. (Reprinted with permission from Dutton RP. Shock and trauma anesthesia. In: Grande CM, Smith CE, eds. *Anesthesiology Clinics of North America: Trauma*. Philadelphia, 1999, WB: Saunders; 83–95.)

decompensation because a fixed stroke volume inhibits the body's ability to increase blood flow in response to hypovolemia and anemia. Tachycardia is the patient's only option, with potentially disastrous consequences on the oxygen supply-demand balance in the heart. Therefore shock in older patients may be rapidly progressive and not respond predictably to fluid administration.[106]

The *lung* is the filter for the inflammatory by-products of the ischemic body. Immune complex and cellular factors accumulate in pulmonary capillaries and lead to neutrophil and platelet aggregation, increased capillary permeability, destruction of lung architecture, and acute respiratory distress syndrome (ARDS).[107,108] The lung is the sentinel organ for the development of multiple organ dysfunction (MOD) in a patient with traumatic shock.[109,110] Pure hemorrhage, in the absence of hypoperfusion, does not produce pulmonary dysfunction.[111] Traumatic shock is obviously more than just a hemodynamic disorder.

The *gut* is one of the earliest organs affected by hypoperfusion and may be one of the prime triggers of MOD. Intense vasoconstriction occurs early and frequently leads to a no-reflow phenomenon, even when the macrocirculation is restored.[112] Intestinal cell death causes a breakdown in the barrier function of the gut that results in increased translocation of bacteria to the liver and lung, thereby potentiating MOD and ARDS.[113]

The *liver* has a complex microcirculation and may experience reperfusion injury during recovery from shock.[114] Hepatic cells are also metabolically active and contribute to the ischemic inflammatory response and to irregularities in blood glucose.[115] Failure of synthetic function of the liver after shock is almost always lethal.

Skeletal muscle is not metabolically active during shock and tolerates ischemia better than do the other organs. The large mass of skeletal muscle, though, makes it important in the generation of lactic acid and free radicals from ischemic cells. Sustained ischemia of muscle cells leads to an increase in intracellular sodium and free water, with an aggravated depletion of fluid in the vascular and interstitial compartments.[116]

More recently, there appears to be a role for endothelial injury in the pathophysiology of hemorrhagic shock. The *endothelium* is one of the "largest" organs in the body with a surface area of up to 5000 m^2.[117] Under normal conditions the endothelium is anticoagulated by a number of natural anticoagulant systems including the negatively charged luminal surface layer, the glycocalyx, which is rich in heparinoids and interacts with antithrombin.[118] As noted earlier, increasing injury severity and shock lead to high catecholamine levels which can directly injure the endothelium.[119] This is evidenced by an increase in syndecan-1 levels, a marker of endothelial glycocalyx degradation.[120,121] The release of heparin-like substances in the glycocalyx may also contribute to endogenous heparinization and the coagulopathy of trauma (discussed in the next section).[122-124] The net effect of this endothelial injury results in glycocalyx shedding, breakdown of tight junctions with capillary leakage, and a pro-coagulant microvasculature that further reduces oxygen delivery due to increased tissue pressure and microvascular thrombosis.

ACUTE TRAUMATIC COAGULOPATHY

During resuscitation from hemorrhagic shock, attention must also be directed to avoidance or correction of coagulopathy. In patients with identical injury severity scores (ISS), the presence of coagulopathy is associated with at least a twofold to fourfold increase in mortality[125,126]; thus current resuscitation strategies focus on coagulopathy and shock during the initial and subsequent resuscitation. The presence of trauma-induced coagulopathy—defined as a "multifactorial, global failure of the coagulation system to sustain adequate hemostasis after major trauma"—has an endogenous component linked to hypoperfusion and tissue injury referred to as acute traumatic coagulopathy (ATC).[127] A proposed mechanism for the development of ATC is endothelial activation of protein C secondary to the traumatic inflammatory response described earlier.[128] Activated protein C (APC) is generated by thrombomodulin-thrombin complex production as a result of tissue hypoperfusion. APC inactivates factors Va and VIIIa, and in combination with the reduction in thrombin availability for fibrin formation, supports the development of ATC.[129] Additionally, degradation of the endothelial glycocalyx as a result of hypoperfusion may play a supporting role in ATC.[130]

By clinical definition, ATC starts with the early presence of reduced clot strength as demonstrated by viscoelastic monitoring and changes in laboratory-based coagulation testing associated with an increase in mortality and likelihood of receiving a massive transfusion.[131] Davenport and colleagues[131] proposed a clot amplitude threshold of less than 35 mm at 5 minutes using rotational thromboelastometry (ROTEM) (Tem Innovations, Munich, Germany) analysis, which predicted the subsequent need for a massive transfusion with a detection rate of 77% and false-positive rate of 13% (see also Chapter 50). Similar results have been obtained using RapidTEG (Haemonetics, Niles, IL) viscoelastic testing.[132] Laboratory-based coagulation testing is of limited utility in early detection of ATC because of time considerations. However, Frith and associates found patients with a prothrombin ratio of greater than 1.2 on admission to have larger transfusion requirements and increased mortality.[133] Regardless of the means used to detect coagulopathy in the severely traumatized patient undergoing resuscitation for hemorrhagic shock, the resuscitation itself should include consideration for early treatment of ATC.

In addition to the described cascade, hyperfibrinolysis occurs in some of the more severely injured patients and contributes to ATC.[134-136] The mechanism behind this early fibrinolysis is not clearly understood but may be related to hypoperfusion-induced APC formation resulting in the consumption of plasminogen activator inhibitor. The latter normally serves to downregulate tissue plasminogen activator, which promotes fibrin clot degradation. The reported incidence of hyperfibrinolysis varies significantly based on the methods and cutoffs used to diagnose fibrinolysis, but its presence is clearly associated with the increased mortality and transfusion requirements seen with ATC.

ASSESSMENT OF THE HEMOSTATIC SYSTEM

Given the importance of coagulopathy in the severely injured trauma patient, assessment of the hemostatic system is essential in the early phases of management. This is best accomplished by collecting and integrating information from the four pillars of perioperative coagulation monitoring: (1) medical history, (2) clinical presentation, (3) standard laboratory-based coagulation tests, and (4) viscoelastic monitoring.[137]

Obtaining a focused patient medical history is one of the key pieces for the evaluation of the individual bleeding risk. In some settings, standardized assessments and specific questionnaires can be deployed to raise sensitivity and specificity, resulting in superior detection of hemostasis issues compared to routine coagulation studies alone.[138] The assessment of the clinical phenotypes of bleeding is critical for the differential diagnosis and enables the clinician to differentiate and semi-quantify the underlying coagulation disorder in a very simple and quick fashion. The clinical assessment also helps to put in context abnormal coagulation studies, so that clinical interventions are not based on laboratory values alone. The clinical assessment aims to differentiate whether the cause of bleeding is "surgical" or "nonsurgical." The latter is characterized by a more diffuse pattern. Standard laboratory coagulation tests typically include prothrombin time, international normalized ratio, activated partial thromboplastin time, and platelet count. In some institutions, other laboratory values such as fibrinogen levels, factor XIII, and thrombin time may be part of a routine laboratory coagulation battery. Standard coagulation tests alone play a limited role in the initial diagnostic steps of patients with deranged hemostasis due to trauma. When used in isolation, the standard tests come with significant limitations regarding the detection of extent and origin of a given patient's coagulopathy. These tests allow only the determination of certain questions and are of restricted value. The key restrictions of standard coagulation tests are: delayed results in a dynamic situation, lack of validation, and inability to detect both hyperfibrinolysis and hypercoagulability. A recent meta-analysis concluded that standard plasma coagulation tests represent historically established parameters that are not fully supported by evidence for the management of perioperative coagulopathic bleeding.[139] This is where viscoelastic monitoring as the fourth pillar of perioperative coagulation assessment brings added value. Viscoelastic coagulation monitoring devices like RapidTEG and ROTEM assess the whole coagulation process from initial thrombin generation to maximum clot formation up to clot lysis.[140] In contrast to the standard laboratory coagulation tests, TEG and ROTEM have been better validated for the diagnosis of coagulopathy in trauma patients.[141,142] These tests can significantly improve the coagulation assessment and management of a given patient; and they may reduce unnecessary administration of procoagulant substances such as platelets, fresh frozen plasma (FFP), and coagulation factor concentrates. The rapid turnaround for results may further enable the anesthesiologist to distinguish between a surgical cause of bleeding and trauma-associated coagulopathy.

GENERAL APPROACH TO RESUSCITATION

Fluid administration is the cornerstone of resuscitation (see also Chapters 47 and 86). Intravascular volume is lost to hemorrhage, uptake by ischemic cells, and extravasation into the interstitial space. Administration of intravenous fluids will predictably increase cardiac output and arterial blood pressure in a hypovolemic trauma patient. The ATLS curriculum initially advocated rapid infusion of up to 2 L of warmed isotonic crystalloid solution in any hypotensive patient, with the goal of restoring normal arterial blood pressure. More recently, this has been revised to recognize the importance of a balanced resuscitation with elimination of the emphasis on a more aggressive approach. The current recommendation suggests initiation of resuscitation with 1 L of crystalloid and earlier use of blood and blood products for patients in shock.[33]

The change in ATLS recommendations recognizes that aggressive crystalloid fluid resuscitation during active hemorrhage may be counterproductive. Dilution of red cell mass reduces oxygen delivery and contributes to hypothermia and coagulopathy. Increased arterial blood pressure may lead to increased bleeding because of disruption of clots and reversal of compensatory vasoconstriction.[143] The result of aggressive fluid administration is often a transient increase in arterial blood pressure, followed by increased bleeding, another episode of hypotension, and the need for more volume administration. This vicious circle has been recognized since the First World War and remains a complication of resuscitation therapy today. The ATLS manual characterizes such patients as "transient responders" with active, ongoing hemorrhage.[33] Resuscitation of these patients should be considered in the following three phases (Table 66.2):

- Phase 1, Uncontrolled Hemorrhage: ongoing active bleeding with focus on damage control with pragmatic resuscitation;
- Phase 2, Controlled Hemorrhage: major bleeding sources under control with focus on goal-directed and tailored management of coagulopathy and resuscitation;
- Phase 3, Restoration of Physiology: hemorrhage has been fully controlled with focus on end-organ perfusion and optimization of physiologic state.

Managing late resuscitation (phase 3) is driven by endpoint targets and consists of giving enough fluid to optimize oxygen delivery. Early resuscitation (phase 1) is much more complex because the risks associated with aggressive intravascular volume replacement (Box 66.5), including the potential for exacerbating hemorrhage and prolonging the crisis, must be weighed against the risk for hypoperfusion and ischemia. These phases do not always have distinct transitions and tend to occur as gradual transitions from initial presentation to the OR and ultimately to the ICU.

Phase 1: Uncontrolled Hemorrhage

During the initial phase of management, the goal in trauma patients with massive hemorrhage requiring an emergent surgical procedure in the OR is to stop the bleeding as soon as possible. In this setting, there is little opportunity to perform additional studies, await test results, or evaluate for perioperative optimization. The role of the anesthesia team is to help achieve hemostasis as quickly as possible, while bridging the patient's physiologic status to allow for surgical stabilization. In phase 1, the general approach employs the concept of damage control resuscitation (DCR). DCR combines an empiric hemostatic resuscitation strategy in combination with permissive hypotension during surgical or angioembolization control of ongoing hemorrhage. In combination with surgical approaches incorporating damage control techniques, the initial goal of controlling

TABLE 66.2 Phases of Major Traumatic Resuscitation

	Phase 1	Phase 2	Phase 3
Clinical status	■ Life-threatening uncontrolled hemorrhage	■ Ongoing hemorrhage—not immediately life-threatening—partial surgical control	■ Hemorrhage controlled
Clinical priorities	■ STOP THE BLEEDING ■ Call for HELP ■ Control airway, FiO2 1.0 ■ Damage control resuscitation ▪ SBP <100 mm Hg ▪ MAP 50-60 mm Hg ▪ Consider modifications if TBI, carotid stenosis, CAD	■ TAILORED RESUSCITATION ■ Place supportive lines (arterial/CVC) ■ Prevent hypothermia ▪ Esophageal temperature probe ▪ Warmed fluids ▪ Warming blankets (upper/lower) ▪ Increase room temperature	■ RESTORE PHYSIOLOGY ■ Rapid intravascular filling ■ Stepwise deepening of anesthesia ▪ Fentanyl boluses ▪ Increased volatile anesthetics ■ Additional lines (urinary catheter, nasogastric tube) ■ Communicate with all team members and ICU
Blood products	■ Activate MTP ■ Consider emergency (uncrossmatched blood products ■ Early use ■ Empiric 1:1:1 ratio (PRBC:FFP:platelets)	■ Viscoelastic monitoring to guide coagulation products ■ Hb to guide red blood cell transfusion	■ Only as required on testing ■ Deactivate MTP when appropriate
Crystalloids/colloids	■ Cautious use	■ Use for hypovolemia with normal coagulation/Hb ■ User serial lactate/BD to guide fluid requirements	■ Attempt to normalize lactate/BD
Special points	■ Consider $CaCl_2$ 1 g for every three PRBC ■ Large bore IV access (>16 G) or CVC ■ Rapid infusing system ■ Avoid vasoconstrictors	■ Consider cell salvage if appropriate ■ Aim to repeat viscoelastic testing every 30 min ■ Consider TEE for difficult cases	■ Consider vasoactive infusions if appropriate/necessary

BD, Base deficit; *CAD*, coronary artery disease; *CVC*, central venous catheter; *FFP*, fresh frozen plasma; *FiO2*, fraction inspired oxygen; *Hb*, hemoglobin; *ICU*, intensive care unit; *IV*, intravenous; *MAP*, mean arterial pressure; *mm Hg*, millimeters of mercury; *MTP*, massive transfusion protocol; *PRBC*, packed red blood cells; *SBP*, systolic blood pressure; *TBI*, traumatic brain injury; *TEE*, transesophageal echocardiography

BOX 66.5 **Risks of Aggressive Volume Replacement during Early Resuscitation**

Increased blood pressure
Decreased blood viscosity
Decreased hematocrit
Decreased clotting factor concentration
Greater transfusion requirement
Disruption of electrolyte balance
Direct immune suppression
Premature reperfusion
Increased risk for hypothermia

Most complications of volume resuscitation arise from increased hemorrhage volume or excessive hemodilution.

hemorrhage, physiologic stabilization, and correction of coagulopathy allows for more definitive surgical interventions later.

Permissive Hypotension. In the setting of trauma, "permissive" rather than "deliberate" hypotension is controversial and has been the focus of numerous laboratory and clinical research efforts. Deliberate hypotensive management is an accepted standard of anesthetic care for elective surgical procedures such as total joint replacement, spinal fusion, radical neck dissection, reconstructive facial surgery, and major pelvic or abdominal procedures.[144] Tolerating some degree of hypotension in the trauma patient during or prior to control of hemorrhage has been more controversial.

In 1965, Shaftan and colleagues[145] published the results of a study of coagulation in dogs that demonstrated that the formation of a soft extraluminal clot limits bleeding after arterial trauma. This study compared the quantity of blood lost from a standardized arterial injury under a variety of conditions. The least blood loss occurred in hypotensive animals (whether hypotensive from hemorrhage or from administration of a vasodilator), followed by the control group and then vasoconstricted animals. The largest amount of blood was lost in animals that underwent vigorous reinfusion during the period of hemorrhage.

Laboratory data have shown the benefits of limiting intravascular fluid volumes and blood pressure in actively hemorrhaging animals.[146-149] In the most sophisticated models, direct assessment of cardiac output and regional perfusion showed no difference between moderate-volume or large-volume resuscitation in terms of cardiac output, arterial blood pressure, or regional perfusion of the heart, kidneys, and intestines. Burris and co-workers[150] studied both conventional resuscitation fluids and various combinations of hypertonic saline and dextran and found that rebleeding was correlated with higher mean arterial pressure (MAP) and that survival was best in groups resuscitated to lower than normal MAP. The optimum target blood pressure for resuscitation varied with the composition of the fluid used. A 1994 consensus panel on resuscitation from hemorrhagic shock noted that mammalian species are capable of sustaining MAP as low as 40 mm Hg for periods as long as 2 hours without deleterious effects. The panel concluded that spontaneous hemostasis and long-term survival were maximized by reduced administration of resuscitation fluids during the period of active bleeding to keep perfusion only just above the threshold for ischemia.[151]

Hypotensive resuscitation has increasingly been accepted as a component of early DCR to avoid excessive administration of fluid until control of active hemorrhage has been achieved. This strategy uses less fluids and blood products during the early stages of treatment for hemorrhagic shock compared with the standard of care.[152] Hypotensive resuscitation has also been shown to be feasible and safe during early resuscitation of trauma patients in the prehospital and hospital settings.[154-157] Early trials suggested outcomes were improved in patients with penetrating trauma[155,156] with no evidence for worsened outcomes in those with blunt trauma.[157]

Initial work by Bickell and colleagues in 1994 randomized victims of penetrating torso trauma to one of two treatment groups: standard of care (up to 2 L of crystalloid infused in the prehospital setting) or delayed resuscitation (no fluid until the patient reached the OR).[155] This well-managed 37-month study eventually included 598 patients. Average times of transport and care were 30 minutes from injury to the ED and then 50 minutes before reaching the OR; the fluid-restricted group received an average of about 0.8 L of fluid during this time. The immediate-resuscitation group received an average of 2.5 L of crystalloid and 130 mL of blood over this same period. Although substantially different during the period of study, blood pressure on arrival at the OR was similar in both groups, which the authors took as evidence that the unresuscitated group had achieved spontaneous hemostasis. Survival to hospital discharge in the delayed-resuscitation group was significantly improved over the immediate-resuscitation group (70% vs. 62% [$P < .04$]). No data were presented on the conduct of anesthesia after arrival at the OR, but before control of hemorrhage, or on the incidence of rebleeding after volume loading and induction of anesthesia in patients who had achieved hemostasis preoperatively.

A retrospective review of trauma admissions to the Los Angeles Medical Center published in 1996 supported these findings. Patients brought to the hospital by private conveyance fared substantially better than those delivered by paramedics, even with high levels of injury severity.[156] Further corroboration was provided by retrospective examination of outcomes in a population of hemorrhaging trauma patients who received fluids via a commercial rapid infusion system (RIS, Haemonetics, Niles, IL) during initial resuscitation.[158] The survival rate of this group was compared with that predicted by the institution's trauma registry. Patients who received fluid by the rapid infusion system, when compared with case-matched controls, had a survival rate of only 56.8% versus 71.2% for patients of similar age with similar injuries ($P < .001$).

This retrospective review was followed in 2002 by the second prospective trial of delayed resuscitation in trauma patients.[157] Patients with systolic blood pressure lower than 90 mm Hg and clinical evidence of blood loss were randomized to fluid resuscitation titrated to a systolic blood pressure of 100 mm Hg (normal group) or 70 mm Hg (study group) until the end of surgical interventions to control hemorrhage. The results of this study are summarized in Table 66.3. As in the Bickell study, hypotension allowed spontaneous resolution of hemorrhage and autoresuscitation; blood pressure would increase without exogenous fluid

TABLE 66.3 Results of a Randomized Trial of Deliberate Hypotensive Resuscitation

	Conventional	Hypotensive	Total
Patients enrolled	55	55	110
Male	46	41	87
Blunt trauma	22	31	53
Penetrating trauma	33	24	57
Injury severity score	19.65	23.62 (*P* = .11)	
Predicted survival	0.94	0.90 (*P* = .19)	
SBP during study period	114	100 (*P* < .001)	
Survived to discharge	51	51	
Died	4	4	

Probability of survival was calculated based on published historical data. *SBP*, Systolic blood pressure.

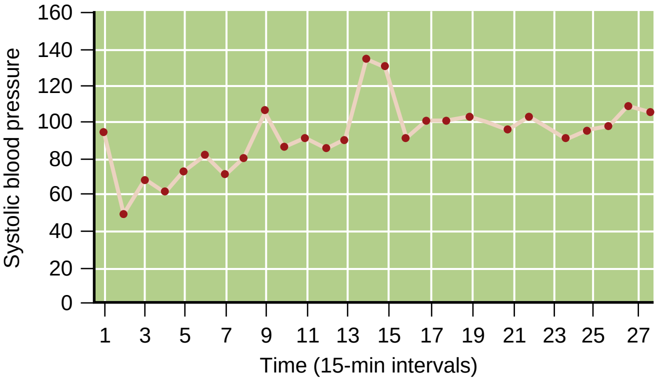

Fig. 66.7 Typical systolic blood pressure measurements of a patient undergoing damage control surgery for a grade V liver injury during deliberate hypotensive management. Oscillations of blood pressure are common during early resuscitation as a result of ongoing hemorrhage and bolus fluid administration. Once hemorrhage is controlled, blood pressure will stabilize.

administration once hemostasis was achieved. The typical patient began with a low initial pressure, followed by recovery to the vicinity of the target, overshoots and undershoots as bleeding and fluid administration continued, and an eventual rise above the target when the hemorrhage resolved, even in the absence of further fluid administration (Fig. 66.7). The 93% overall survival rate in this study was more frequent than predicted from historical data and substantially more frequent than seen in Bickell's group. This reflects the exclusion of patients who died in the prehospital phase or arrived at the trauma resuscitation unit in a moribund condition. It may also reflect improvements in overall care, an observation effect (i.e., patients in both groups received better care than did patients not in the study), or a bias in subject recruitment. Over the first 24 hours, lactate and base deficit cleared to normal in both groups and required similar amounts of fluid and blood products, thus suggesting that both groups were reaching an equivalent resuscitation endpoint. The authors concluded that administration of fluids to an actively hemorrhaging patient should be titrated to specific physiologic endpoints, with the anesthesiologist navigating a course between the Scylla of increased hemorrhage and the Charybdis of hypoperfusion.

TABLE 66.4 Differences in Presentation Between Surgical Patients Undergoing Elective Deliberate Hypotension and Emergency Trauma Cases

Aspect	Elective	Trauma
Intravascular volume	Euvolemic	Hypovolemic
Temperature	Normal	Likely hypothermic
Capillary beds	Dilated	Constricted
Level of general anesthesia	Deep	Usually light
Preexisting mental status	Normal	May be impaired
Coexisting injuries	None	May be significant
Comorbid conditions	Known and managed	Unknown

Each of these factors produces a real or perceived contraindication to the use of deliberate hypotensive technique in the trauma patient.

In a more recent study, Morrison and colleagues compared a hypotensive resuscitative strategy targeting a MAP of 50 mm Hg to one targeting a MAP of 65 mm Hg with conventional resuscitation for patients requiring emergent surgery.[152] In a preliminary report, they found that patients in the hypotensive resuscitation group had a lower, early postoperative mortality, a reduced incidence of coagulopathy, and lower mortality related to coagulopathy. Subsequently, this study was terminated early for futility and clinical equipoise with no significant survival advantage and similar rates of coagulopathy, renal failure, and infection between the low (50 mm Hg) and high (65 mm Hg) MAP target groups.[159] Of note, this study excluded blunt trauma patients included in the preliminary report.[152] Despite not identifying a difference in major outcomes, the authors did make several interesting observations. First, the need for vasopressors use in the first hour of surgery was greater in the high MAP group. Although this group also received more fluid, it was not statistically significant. Second, the intraoperative MAP was not significantly different between the low and high MAP groups (65.5 ± 11.6 mm Hg vs. 69.1 ± 13.8 mm Hg, *P* = .07, respectively). Taken in combination with available data and experience, the current consensus at major trauma centers is to allow for hypotensive resuscitation in the setting of DCR barring specific caveats discussed below. While the optimal arterial blood pressure remains controversial, a reasonable approach is to target a systolic pressure of less than 100 mm Hg with MAP between 50 to 60 mm Hg.[160]

As a component of intraoperative management, the effect of anesthetic drugs on the body's response to hemorrhage is an important difference between deliberate hypotension occurring in the elective operative setting and hemorrhagic shock occurring in the ED. Trauma patients who are hypertensive receive a minimum of anesthetics, even for induction of anesthesia, because of the obvious effect of these drugs on arterial blood pressure. A hypotensive trauma patient is thus in a state of profound vasoconstriction, as opposed to a patient undergoing elective intraoperative hypotension who is vasodilated by general anesthesia before any blood loss. Table 66.4 summarizes the physiologic contrasts between these two states. It should be noted that blood loss without shock does not produce systemic

BOX 66.6 Goals for Early Resuscitation

- Maintain systolic blood pressure of 80-100 mm Hg
- Maintain hematocrit of 25%-30%
- Maintain prothrombin time and partial thromboplastin time in normal ranges
- Maintain platelet count at greater than 50,000 per high-power field
- Maintain normal serum ionized calcium
- Maintain core temperature higher than 35°C
- Maintain function of pulse oximeter
- Prevent increase in serum lactate
- Prevent acidosis from worsening
- Achieve adequate anesthesia and analgesia

Fluid administration to limit hypoperfusion is balanced against an undesirable increase in blood pressure and thus bleeding.

complications such as ARDS in experimental models.[111] Based on this physiology, the recommended goals for early resuscitation are expressed in Box 66.6, and an algorithm for management is presented in Figure 66.2. The emphasis in this situation must be on rapid diagnosis and control of ongoing hemorrhage; vascular volume should be restored and anesthesia provided together by shifting the patient from a vasoconstricted to a vasodilated state while facilitating hemostasis by maintenance of a decreased arterial blood pressure.

Clinical trials of permissive hypotensive resuscitation have avoided the application of this technique to populations perceived to be at greater risk for ischemic complications,[155,157] including patients with known ischemic coronary disease, older patients, and those with injuries to the brain or spinal cord. The prohibition against hypotension in patients with TBI is especially well established because of the observed disparity in outcome between TBI patients who experience hypotension and those who do not.[161,162] Older trauma patients suffer worse outcomes from similar injuries than younger patients, presumably because of their reduced physiologic reserve.[163] Clinical care of these patients is focused on avoidance of ischemic stress and rapid correction of hypovolemia. It may well develop, however, that permissive hypotensive management to enable rapid control of hemorrhage is equally beneficial in vulnerable populations. No clinical trials to date have been conducted on this subject, but a laboratory study did find a benefit of permissive hypotension in animals with both TBI and hemorrhagic shock.[164] Absent convincing evidence in humans, permissive hypotension in older patients or patients with brain injury should generally be avoided.

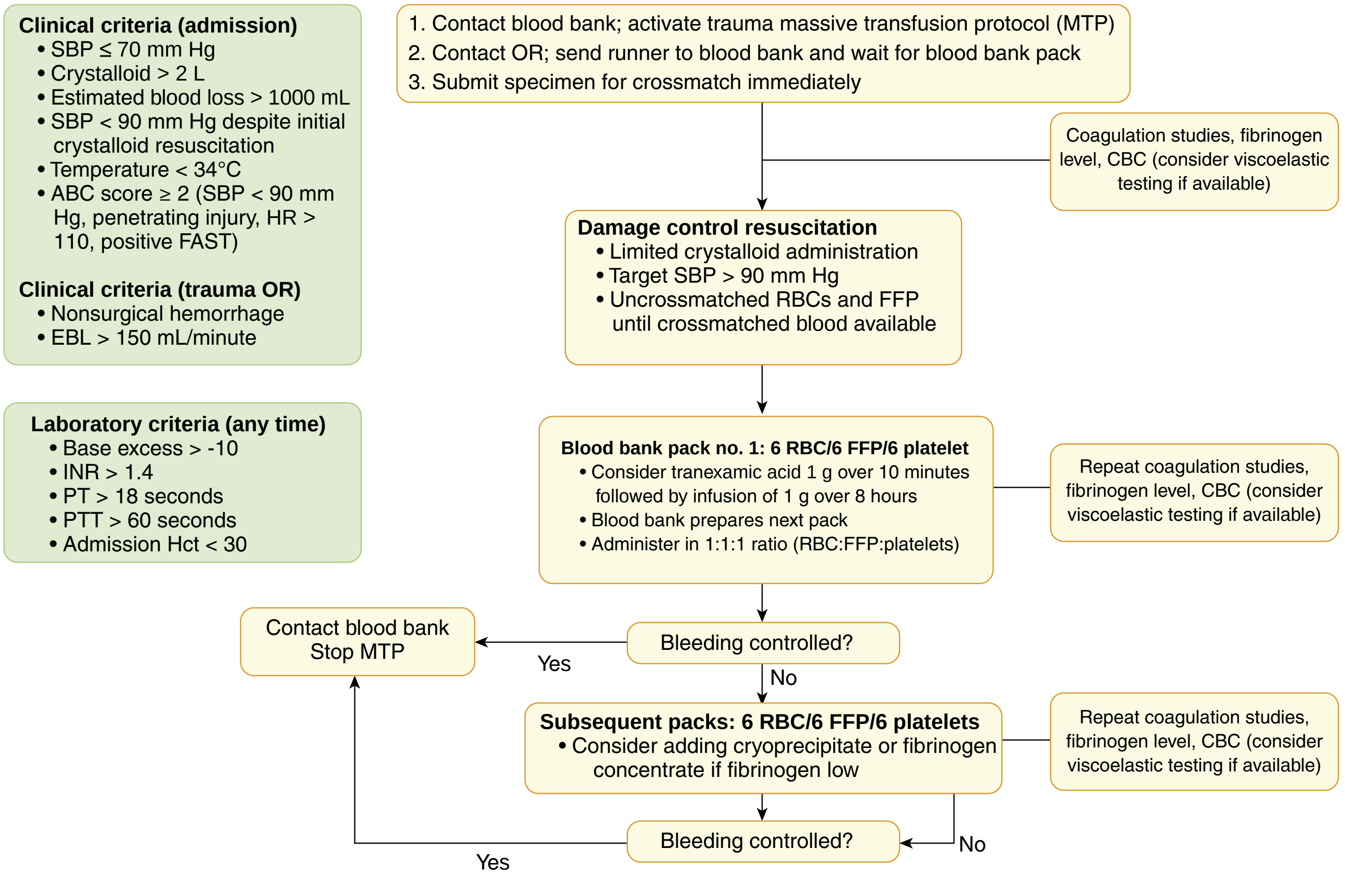
Hemostatic Resuscitation. As discussed earlier, management of the early coagulopathy associated with trauma must be incorporated into the overall phase 1, Uncontrolled Hemorrhage DCR strategy—often referred to as a hemostatic resuscitation. Little utility is found in targeting endpoints of resuscitation in the face of ongoing hemorrhage. Life-threatening coagulopathy is one of the most serious complications of patients in profound shock from massive hemorrhage and is generally predictable at an early stage.[165]

Because of evidence that severely injured trauma patients are likely to develop an early and aggressive endogenous coagulopathy separate from later loss and dilution of clotting factors compounded from hypothermia and acidosis,[126,128,166] the practice of hemostatic resuscitation has become commonplace in the most severely injured patients with shock and ongoing hemorrhage. This entails the early and aggressive use of hemostatic products combined with red blood cells (RBCs) as the primary resuscitation fluids to avoid rapid deterioration into the "bloody vicious cycle" and the classic lethal triad of hypothermia, acidosis, and coagulopathy.[167] Two very distinct paradigms of hemostatic resuscitation have emerged: (1) the DCR model, which uses preemptive administration of empiric ratios of blood and hemostatic products to approximate whole blood, often according to an established institutional massive transfusion protocol (Fig. 66.8)[168-170]; and (2) goal-directed hemostatic resuscitation approaches (also often protocol based), which generally use point-of-care viscoelastic monitoring combined with the prompt administration of hemostatic concentrates.[171-173] The DCR model is typically employed during phase 1, Uncontrolled Hemorrhage, with a transition to more goal-directed hemostatic resuscitation during phase 2, Controlled Hemorrhage.

In addition to the use of permissive hypotension and limited crystalloid usage, DCR relies on the administration of empiric ratios of blood and hemostatic products to restore blood volume. In a retrospective review of combat casualties, Borgman and colleagues[174] found a mortality rate of 65% in patients receiving less than 1 unit plasma for every 4 units RBCs, but only 20% in those with a ratio of 1:2 or above. Evidence exists of a survivor bias because patients bleeding more rapidly were likely to die after receiving RBCs but before plasma could reach the bedside. Although the issue of a survivor bias does exist, this approach has been substantiated in published reviews.[174,175] Currently a ratio of 1:1:1 is most commonly adopted, although some experts believe that the amount of FFP can be reduced in most cases. In the only major, randomized trial comparing a 1:1:1 ratio with a 1:1:2 ratio of plasma, platelets, and RBCs, respectively, the transfusion of less plasma and platelets was not associated with a difference in mortality although the 1:1:1 group achieved hemostasis more rapidly and had fewer deaths due to exsanguination by 24 hours.[176]

In addition to the hypocoagulability associated with ATC, fibrinolysis is especially deleterious in severely injured trauma patients and carries an associated mortality well upward of 50%.[177,178] Many patients with primary fibrinolysis from severe hemorrhagic shock may never survive to reach the ICU. The Clinical Randomisation of an Antifibrolytic in Significant Haemorrhage 2 trial is the only class I evidence showing a 30-day survival benefit for a resuscitative therapy including tranexamic acid (TXA).[179] Subgroup analysis showed that the benefit was greatest when therapy was instituted within 1 hour of admission. A subsequent analysis, however, showed that mortality increased when therapy was instituted after 3 hours, suggesting that the risks of therapy outweighed the benefits in patients who survived beyond that timeframe.[180] Many resuscitative protocols for massive hemorrhage now include the early administration of TXA based on this and subsequent studies.[181]

Other potential drugs that may play a role in hemostatic resuscitation include recombinant activated human coagulation factor VII (rFVIIa), prothrombin complex



Clinical criteria (admission)
• SBP ≤ 70 mm Hg
• Crystalloid > 2 L
• Estimated blood loss > 1000 mL
• SBP < 90 mm Hg despite initial crystalloid resuscitation
• Temperature < 34°C
• ABC score ≥ 2 (SBP < 90 mm Hg, penetrating injury, HR > 110, positive FAST)
Clinical criteria (trauma OR)
• Nonsurgical hemorrhage
• EBL > 150 mL/minute
Laboratory criteria (any time)
• Base excess > -10
• INR > 1.4
• PT > 18 seconds
• PTT > 60 seconds
• Admission Hct < 30
1. Contact blood bank; activate trauma massive transfusion protocol (MTP)
2. Contact OR; send runner to blood bank and wait for blood bank pack
3. Submit specimen for crossmatch immediately
Coagulation studies, fibrinogen level, CBC (consider viscoelastic testing if available)
Damage control resuscitation
• Limited crystalloid administration
• Target SBP > 90 mm Hg
• Uncrossmatched RBCs and FFP until crossmatched blood available
Blood bank pack no. 1: 6 RBC/6 FFP/6 platelet
• Consider tranexamic acid 1 g over 10 minutes followed by infusion of 1 g over 8 hours
• Blood bank prepares next pack
• Administer in 1:1:1 ratio (RBC:FFP:platelets)
Repeat coagulation studies, fibrinogen level, CBC (consider viscoelastic testing if available)
Contact blood bank
Stop MTP
Yes
Bleeding controlled?
No
Subsequent packs: 6 RBC/6 FFP/6 platelets
• Consider adding cryoprecipitate or fibrinogen concentrate if fibrinogen low
Repeat coagulation studies, fibrinogen level, CBC (consider viscoelastic testing if available)
Bleeding controlled?
No
Yes

concentrates (PCCs), and fibrinogen concentrates. rFVIIa is licensed for the treatment of patients with hemophilia with active or anticipated hemorrhage and known antibodies to factor VIII. The observation of rapid hemostasis in this population led to the anecdotal use of rFVIIa in other congenital and acquired coagulopathies, including the dilutional coagulopathy of traumatic hemorrhage. Factor VIIa in pharmacologic doses works by triggering a burst of thrombin on the surface of platelets activated by exposed tissue factor, which produces rapid clot formation. Because tissue factor is required, coagulation is limited to the site of vascular injury, and inappropriate clotting of uninjured organs or vessels, though an acknowledged risk, occurs at only low frequency.[182] One small placebo-controlled trial of rFVIIa in hemorrhaging trauma patients has demonstrated decreased blood loss, decreased transfusion requirements, and improved outcome,[183] although a large, randomized trial failed to show a mortality benefit.[184] In combination with an increased risk for thromboembolic adverse events,[185] this lack of clear efficacy has contributed to decreased utilization of rFVIIa as an empiric therapy in the management of the bleeding trauma patient.

Experience with PCCs in clinical practice is limited. PCC has been used for many years for the treatment of congenital coagulation disorders and is recommended for reversing oral anticoagulation, particularly in the setting of traumatic intracranial hemorrhage. PCCs contain coagulation factors II, VII, IX, and X. Differences exist among products in the concentrations of these factors and other constituents, including heparin, protein C, and protein S, so results obtained with one product may not be obtained with a different formulation. Fibrinogen concentrates also may have a role in a hemostatic resuscitation for the patient with a coagulopathy with low levels of fibrinogen.[186-188]

Phase 2, Controlled Hemorrhage

Once major aspects of bleeding have been controlled, a more individualized, tailored approach to resuscitation can generally be employed by the anesthesia team. In phase 2, there should be increased utilization of point-of-care testing such as arterial blood gas and other laboratory test results, viscoelastic monitoring parameters, and physiologic data to drive decision-making. Assessment of oxygen delivery and adequacy of perfusion can start to incorporate some targeted resuscitation measures such as lactate and base deficit. Use of other monitoring modalities such as transesophageal echocardiography (TEE) or transthoracic echocardiography (TTE) may be useful in quantifying and guiding the need for further intravascular volume replacement.

While surgical bleeding may be corrected at this time, the depth and duration of shock in combination with multisystem trauma may still contribute to coagulopathy. This will require ongoing assessment such as serial evaluations with viscoelastic coagulation monitoring. Transition from empiric replacement of FFP and platelets toward a more

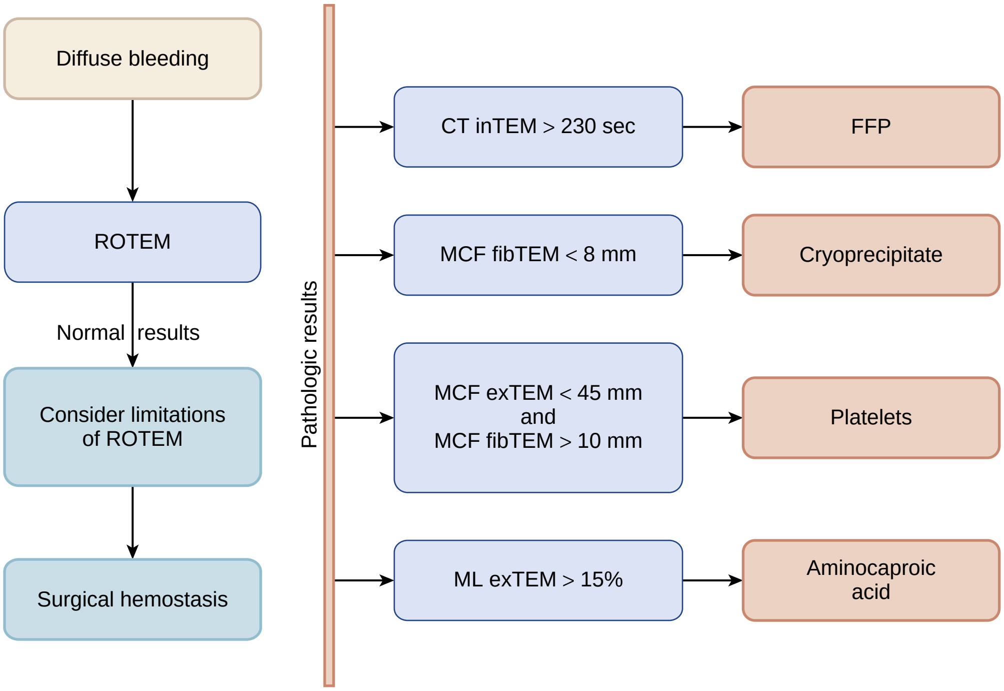

Fig. 66.9 Example of a rotation thromboelastometry *(ROTEM)* treatment algorithm for use in trauma. *CT,* Clotting time; *FFP,* fresh frozen plasma; *MCF,* maximum clot firmness; *ML,* maximum lysis. Philadelphia: Elsevier; 2018:724 [Chapter 42].)

tailored approach can be accomplished using an algorithm (Fig. 66.9) to guide specific product selection and limit exposure to unnecessary blood products.

Additionally, during this time, attention to other physiologic considerations can proceed. For example, hypothermia is commonly present on initial presentation. During phase 1, all attempts should be made to initiate active fluid and surface warming although it is difficult to fully correct during a massive resuscitation. During phase 2, additional measures can be instituted as the focus shifts from control of hemorrhage to stabilization of all physiologic processes.

Phase 3, Restoration of Physiology

Box 66.7 summarizes endpoints for late resuscitation, and Fig. 66.10 presents an algorithm for management. Intravenous fluid administration is an integral, mandatory component. The adequacy of resuscitation should not be judged by the presence of normal vital signs, but by restoration of organ and tissue perfusion. The role of the anesthesiologist-intensivist is to recognize the presence of ongoing shock after traumatic hemorrhage and to resuscitate the patient with the appropriate type and amount of fluids intravenously at the appropriate time.

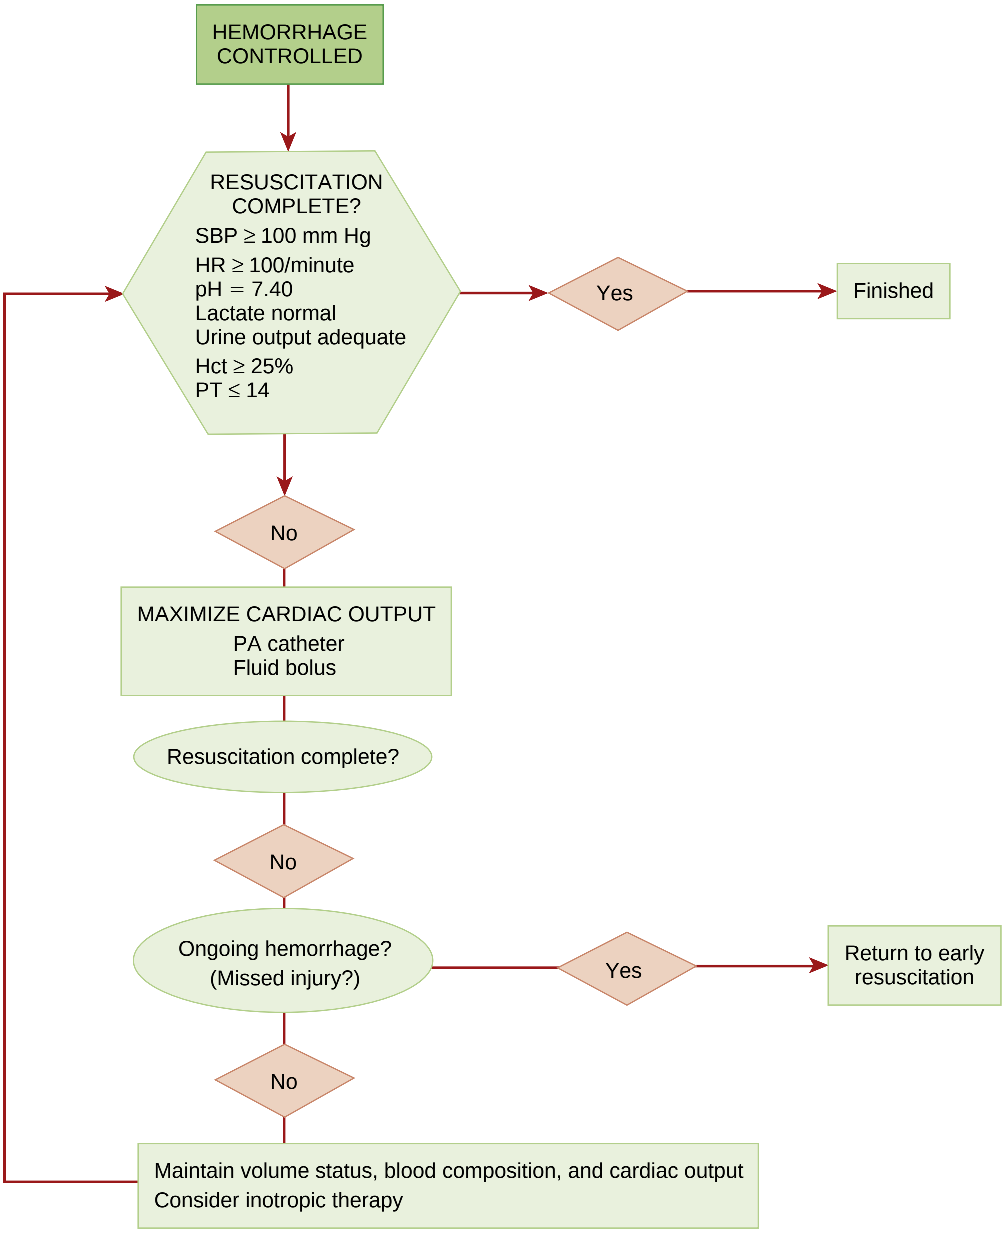
Late resuscitation begins once bleeding is definitively controlled by surgery, angiography, or the passage of time. The goal at this time is to restore normal perfusion to all organ systems while continuing to support vital functions. Hypoperfusion caused by hemorrhagic shock triggers a predictable cascade of biochemical events that will cause physiologic derangements persisting long after adequate blood flow is restored. The extent of hypoperfusion—the depth and duration of shock—dictates the magnitude of subsequent organ system failure. Unfortunately, traditional vital sign markers such as arterial blood pressure, heart rate, and urine output are insensitive to the adequacy of resuscitation. Occult hypoperfusion syndrome is common in postoperative trauma patients, particularly young ones.[189] This syndrome is characterized by a normal blood pressure maintained by systemic vasoconstriction, decreased intravascular volume and cardiac output, and organ system ischemia. The patient will be at frequent risk for MOD if the hypoperfusion is not promptly corrected.

BOX 66.7 **Goals for Late Resuscitation**

Maintain systolic blood pressure higher than 110 mm Hg
Maintain hematocrit above individual transfusion threshold
Normalize coagulation status
Normalize electrolyte balance
Normalize body temperature
Restore normal urine output
Maximize cardiac output by invasive or noninvasive measurement
Reverse systemic acidosis
Document decrease in lactate to normal range

Fluid administration should be continued until adequate systemic perfusion is restored.

The search for the optimal endpoints of resuscitation has led to several different hemodynamic, acid-base, and regional perfusion targets. Table 66.5 summarizes modalities that are available to gauge the adequacy of resuscitation, along with the shortcomings of each technique. Although the flow of blood to tissue beds is a determinant of tissue perfusion, pressure should also be an important consideration. The left ventricular stroke work index is a variable that accounts for both flow and pressure. Furthermore,



HEMORRHAGE CONTROLLED
RESUSCITATION COMPLETE?
SBP ≥ 100 mm Hg
HR ≥ 100/minute
pH = 7.40
Lactate normal
Urine output adequate
Hct ≥ 25%
PT ≤ 14
Yes
Finished
No
MAXIMIZE CARDIAC OUTPUT
PA catheter
Fluid bolus
Resuscitation complete?
No
Ongoing hemorrhage?
(Missed injury?)
Yes
Return to early resuscitation
No
Maintain volume status, blood composition, and cardiac output
Consider inotropic therapy

Fig. 66.10 Algorithm for management of late hemorrhagic shock. *Hct,* Hematocrit; *HR,* heart rate; *PA,* pulmonary artery; *PT,* prothrombin time; *SBP,* systolic blood pressure.

left ventricular power output has been used to quantify left ventricular performance. These indices were compared with purely flow-derived hemodynamic and oxygen transport variables as markers of perfusion and outcome in critically injured patients during resuscitation.[190] A consecutive series of 111 patients were monitored with a volumetric pulmonary artery catheter during the first 48 hours of resuscitation. The ability to clear lactate in less than 24 hours and survival were studied. Survivors exhibited significantly higher stroke work and left ventricular power output than did nonsurvivors. In addition to heart rate, these were the only variables that were significantly related to lactate clearance and survival. The higher stroke work and left ventricular power output in survivors were related to better ventricular-arterial coupling and therefore more efficient cardiac function.

Monitoring resuscitation with invasive monitors is gradually changing to noninvasive approaches that assess the return of adequate metabolism, respiration, and oxygen transport in peripheral tissue beds. One such technique is tissue oxygen monitoring (skin, subcutaneous tissue, or skeletal muscle). Skeletal muscle blood flow decreases early in the course of shock and is restored later during resuscitation, thus making the skeletal partial pressure of oxygen a sensitive indicator of decreased flow.[191,192] Stroke volume variation, the change in arterial pressure driven by the respiratory cycle, is emerging as another less invasive measure of fluid volume status; increased variation in arterial pressure during positive-pressure ventilation is a reliable predictor of decreased intravascular volume.[193] Inadequate tissue perfusion, as indicated by these specific monitors or by the traditional systemic markers of serum lactate, base deficit,

TABLE 66.5 Modalities for Assessment of Systemic Perfusion

Technique	Shortcomings
Vital signs	Will not indicate occult hypoperfusion
Urine output	May be confounded by intoxication, diuretic therapy, circadian variation, or renal injury
Systemic acid-base status	Confounded by respiratory status
Lactate clearance	Requires time to obtain laboratory result
Cardiac output	Requires placement of a pulmonary artery catheter, or use of noninvasive technology
Mixed-venous oxygenation	Difficult to obtain, but a very accurate marker
Gastric tonometry	Requires time to equilibrate, subject to artifact
Stroke volume variation	Requires an arterial line; may not be accurate in severe shock
Tissue oxygenation	Emerging technology, appears beneficial

and decreased pH, must be treated promptly once ongoing hemorrhage is controlled. The rate at which lactate returns to normal after shock is strongly correlated with outcome; failure to normalize within 24 hours is associated with a greater risk for MOD and eventual death.[189,194]

RESUSCITATION FLUIDS

Isotonic crystalloids (normal saline, lactated Ringer solution, Plasma-Lyte A) are the initial resuscitative fluids administered to any trauma patient (see also Chapter 47). They have the advantage of being inexpensive, readily available, nonallergenic, noninfectious, and efficacious in restoring total body fluid. They are easy to store and administer, they mix well with infused medications, and they can be rapidly warmed to body temperature. Disadvantages of crystalloids include their lack of oxygen-carrying capacity, their lack of coagulation capability, and their limited intravascular half-life. Of note, data have implicated specific crystalloid solutions as immunosuppressants and triggers of cellular apoptosis.[195] Unlike necrosis, apoptosis is highly regulated and involves gene modulation and complex pathways of signal transduction. It seems clear that apoptosis is an important element of reperfusion injury. In a rat model of controlled hemorrhage, animals receiving lactated Ringer solution showed an immediate increase in apoptosis in the liver and small intestine after resuscitation.[196] Neither whole blood nor hypertonic saline increased the amount of apoptosis.

Hypertonic saline solutions, with or without the addition of polymerized dextran (HS or HSD), have been extensively studied in resuscitation from hemorrhagic shock.[197] In theory, HS will draw fluid into the vascular space from the interstitium and thereby reverse some of the nonhemorrhagic fluid loss caused by shock and ischemia. A given amount of HS will thus have an enhanced ability to restore intravascular volume in contrast to an equivalent volume of an isotonic solution. This has made HS a popular choice for fluid resuscitation under austere conditions. HSD is licensed for prehospital use in some European countries and is used for resuscitation by units of the U.S. military. Multiple studies of otherwise lethal hemorrhage in animals have demonstrated improved survival after resuscitation with HSD versus either normal saline solution or the components of HSD alone. Studies of the efficacy of HSD in trauma patients have been inconclusive[198]; the most obvious benefit occurred in a subset of polytraumatized patients with both hemorrhage and TBI, in whom improved neurologic status was demonstrated in those who received HSD as a resuscitation fluid. Indeed, HS is commonly used as an osmotic agent in the management of TBI with increased ICP.[199]

Colloids, including starch solutions and albumin, have been advocated for rapid plasma intravascular volume expansion. Like crystalloids, colloids are readily available, easily stored and administered, and relatively inexpensive. As with hypertonic solutions, colloids will increase intravascular volume by drawing free water back into the vascular space. When intravenous access is limited, colloid resuscitation will restore intravascular volume more rapidly than crystalloid infusion will and at a lower volume of administered fluid. Colloids do not transport oxygen or facilitate clotting; their dilutional effect will be similar to that of crystalloids. Systematic reviews continue to show no benefit of colloids over crystalloids in the setting of trauma resuscitation,[200] although this topic continues to generate significant controversy and would benefit from several well-conducted, randomized trials.[201] Recent concerns, however, have been expressed about specific colloids such as 6% hetastarch and an adverse effect on renal function and mortality (see also Chapter 49).[202-204]

Many of the risks of aggressive intravascular fluid administration just summarized are related to dilution of the circulating blood volume. Recognition of this fact and continued improvement in the safety of donated blood led to increased use of blood products in the management of early hemorrhagic shock (see also Chapter 49). The risk for systemic ischemia is decreased by the maintenance of an adequate hematocrit, and the potential for dilutional coagulopathy can be decreased by the early administration of plasma. The composition of resuscitation fluids may be as important as the rate and timing of administration. A 4-year retrospective review of a cohort of critically injured patients who underwent emergency surgery examined the outcomes of short-term care based on the number of units of blood transfused.[205] One hundred forty-one patients received massive blood transfusions (≥20 units of RBCs) during preoperative and intraoperative resuscitation. The number of blood units did not differ between survivors (30%) and nonsurvivors (70%). Eleven variables were significantly different: aortic clamping for control of arterial blood pressure, use of inotropic drugs, time with a systolic blood pressure higher than 90 mm Hg, time in the OR, temperature less than 34°C, urine output, pH lower than 7.0, PaO_2/FiO_2 ratio less than 150, $PaCO_2$ more than 50 mm Hg, K^+ more than 6 mM/L, and calcium less than 2 mM/L. Of these, the presence of the first three variables in the face of transfusion of more than 30 units of packed RBCs was invariably fatal. Total blood loss and the amount of transfused blood were less critical than the depth and duration of shock. These concerns led to the concept of damage control surgery discussed earlier, which emphasizes rapid control of active hemorrhage.[206]

RBCs are the mainstay of treatment of hemorrhagic shock. With an average hematocrit of 50% to 60%, a unit of RBCs will predictably restore oxygen-carrying capacity and expand intravascular volume as well as any colloid solution. RBCs of blood type A, B, or AB carry major incompatibility antigens that may precipitate a lethal transfusion reaction if given to a patient with the opposite blood type. Because RBCs also carry dozens of minor antigens that can cause reactions in susceptible patients, crossmatching is desirable when time allows (typically 1 hour from the time a sample reaches the blood bank until the RBCs reach the patient). Type-specific blood requires less time for delivery from the blood bank (usually ~30 minutes) and may be an appropriate alternative in some situations. Type O blood—the universal donor type—can be given to patients of any blood type with little risk for a major reaction.[207] This is the preferred approach for patients who arrive at the ED in hemorrhagic shock. If O-positive blood is given to a Rhesus-negative woman who survives, prophylactic administration of anti-Rh_0 antibody is indicated.

Risks of RBC administration include transfusion reaction, transmission of infectious agents, and hypothermia (see also Chapter 49 for details). For example, RBCs are stored at 4°C and will decrease the patient's temperature rapidly if not infused through a warming system at the time of administration.

Plasma requires blood typing but not crossmatching; delay in availability of plasma is caused by the need to thaw frozen units before they can be administered. Busy trauma hospitals will often maintain a supply of prethawed plasma (thawed fresh plasma as opposed to FFP) that can be issued quickly in response to an emergency need; in smaller hospitals it is important to request plasma early in resuscitation if it is likely to be needed. Very busy centers are experimenting with keeping 2 to 4 units of prethawed type AB (universal donor) plasma available in the trauma resuscitation unit. Units are kept ready in this way for 2 days at a time; if not used on an emergency basis, the units are returned to the blood bank and released to the next patient needing plasma. Whether this approach improves outcomes has not yet been studied.

Platelet transfusion should normally be reserved for patients with clinical coagulopathy with a documented low serum level (>50,000 per high-power field). When the patient is in shock, however, and blood loss is likely to be substantial, platelets should be empirically administered in proportion to RBCs and plasma (1:1:1), as discussed earlier for DCR. Transfused platelets have a very short serum half-life and should be administered only to patients with active coagulopathic bleeding. Platelets should not be administered through filters, warmers, or rapid infusion systems because they will bond to the inner surfaces of these devices, thereby reducing the quantity of platelets actually reaching the circulation.

Rapid transfusion of banked blood carries the risk for inducing citrate intoxication in the recipient.[208] Harvested blood units are treated with citrate to bind free Ca^{2+} and thus inhibit the clotting cascade. Consecutive administration of multiple units of banked blood leads to a correspondingly large dose of citrate, which may overwhelm the body's ability to mobilize free Ca^{2+} and have a profound negative inotropic effect on the heart. Unrecognized hypocalcemia is a cause of hypotension in patients after massive transfusion and persists despite an adequate volume of resuscitation. Ionized Ca^{2+} levels should be measured at regular intervals in a hemorrhaging patient, and Ca^{2+} should be administered as needed (in a separate intravenous line from transfusion products) to maintain serum levels greater than 1.0 mmol/L.

RESUSCITATION EQUIPMENT

Intravascular fluid resuscitation of any kind is impossible in the absence of intravenous access. Immediate placement of at least two large-bore catheters (16 gauge or larger) is recommended during the primary assessment of any trauma patient.[33] Practitioners should have a low threshold for placement of a large-caliber central line in any patient in whom antecubital or other peripheral placement attempts have been unsuccessful. Potential sites for central line placement include the internal jugular, subclavian, and femoral veins, each of which has its own benefits and potential risks. The internal jugular approach, though familiar to most anesthesiologists, will require removal of the cervical collar and manipulation of the patient's neck and is not recommended in the acute setting unless other options have been exhausted. The femoral vein is easily and rapidly accessed and is an appropriate choice in patients without apparent pelvic or thigh trauma who require urgent drug or fluid administration. Caution should be used in patients with penetrating trauma to the abdomen because fluids infused via the femoral vein may contribute to hemorrhage from an injury to the inferior vena cava or iliac vein; these patients should have intravenous access placed above the diaphragm if possible. Femoral vein catheterization carries a high risk for the formation of deep venous thrombosis,[209] thus limiting use of this approach to the acute setting. Femoral lines should be removed as soon as possible after the patient's condition stabilizes. The subclavian vein is the most common site for early and ongoing central access in a trauma patient because the subclavian region is easily visible and seldom directly traumatized. This approach carries the highest risk for the development of pneumothorax, although many patients will already have indications for tube thoracostomy in one or both chest cavities; when possible, this is the preferred side for placement of a subclavian line. Placement of an arterial line facilitates frequent laboratory analysis and allows close monitoring of blood pressure; this should be undertaken as soon as possible but should not impede other diagnostic or therapeutic maneuvers.

The anesthesiologist should work to maintain thermal equilibrium in any trauma patient. Although deliberate hypothermia has been suggested as a management strategy for both hemorrhagic shock[210] and TBI,[211] insufficient evidence exists to support this approach. Hypothermia will potentiate dilutional coagulopathy and systemic acidosis while shivering and vasoconstriction in response to cold will demand an additional metabolic effort that may predispose the patient to myocardial ischemia. Hypothermia also greatly increases the subsequent risk for sepsis. Because many trauma patients arrive at the ED cold from exposure to the elements, early active warming measures are required. All IV fluids should be prewarmed or infused through a warming device. The patient should be kept covered with warmed blankets whenever possible, and the environment should be kept warm enough to make the patient comfortable. If hypothermia has already developed, the use of forced hot air warming is strongly indicated to restore normothermia. Even though all these measures are routine and obvious in the OR, the anesthesiologist can perform a valuable service by ensuring that they are available and applied in the ED, CT scanner, and angiography suite as well.

Commercial rapid-infusion devices are of great benefit in trauma care, particularly in the presence of hemorrhagic shock. These machines offer benefits when large quantities of fluid resuscitation are likely (Box 66.8). Early experience with these devices demonstrated higher patient temperature and reduced acidosis at the conclusion of the initial surgery,[212] although rapid infusers may contribute to over infusion of fluids, inappropriately increased arterial blood pressure, and contribute to rebleeding.[158] Application of the principles described earlier for permissive hypotension can prevent this complication; basal fluid administration should be kept low (200-500 mL/h), with fluid boluses given in response to measured systolic blood pressure less than 80 to 90 mm Hg. In practice, fluid boluses are given alternately with anesthetics, with the goal of reaching a normal depth of anesthesia without significantly increasing systolic arterial blood pressure until active bleeding is controlled.

Trauma to the Central Nervous System

CNS trauma accounts for almost half of all trauma deaths after trauma center admission and as indicated by postmortem examinations in population-based analyses (see also Chapter 57).[213,214] In the United States, 2.8 million TBI-related ED visits, hospitalizations, and deaths occurred in 2013.[215] Although not as prevalent, acute traumatic SCI also remains a significant problem.[216] As with hemorrhagic shock, CNS trauma consists of both the primary injury, in which tissue is disrupted by mechanical force, and a secondary response, in which the body's reaction to the injury plays an important role. Mitigation of secondary CNS injury depends on prompt diagnosis and early, goal-directed therapy. Although primary CNS injuries cannot be minimized other than with preventive strategies, secondary injury accounts for much of the death and disability that follows trauma.[217] The initial management of these patients can significantly affect outcome. Attention to the ABCDE approach is paramount to successful resuscitation, and the trauma anesthesiologist should be intimately involved in this process.

BOX 66.8 Benefits of a Fluid Infusion System in Resuscitation from Hemorrhagic Shock

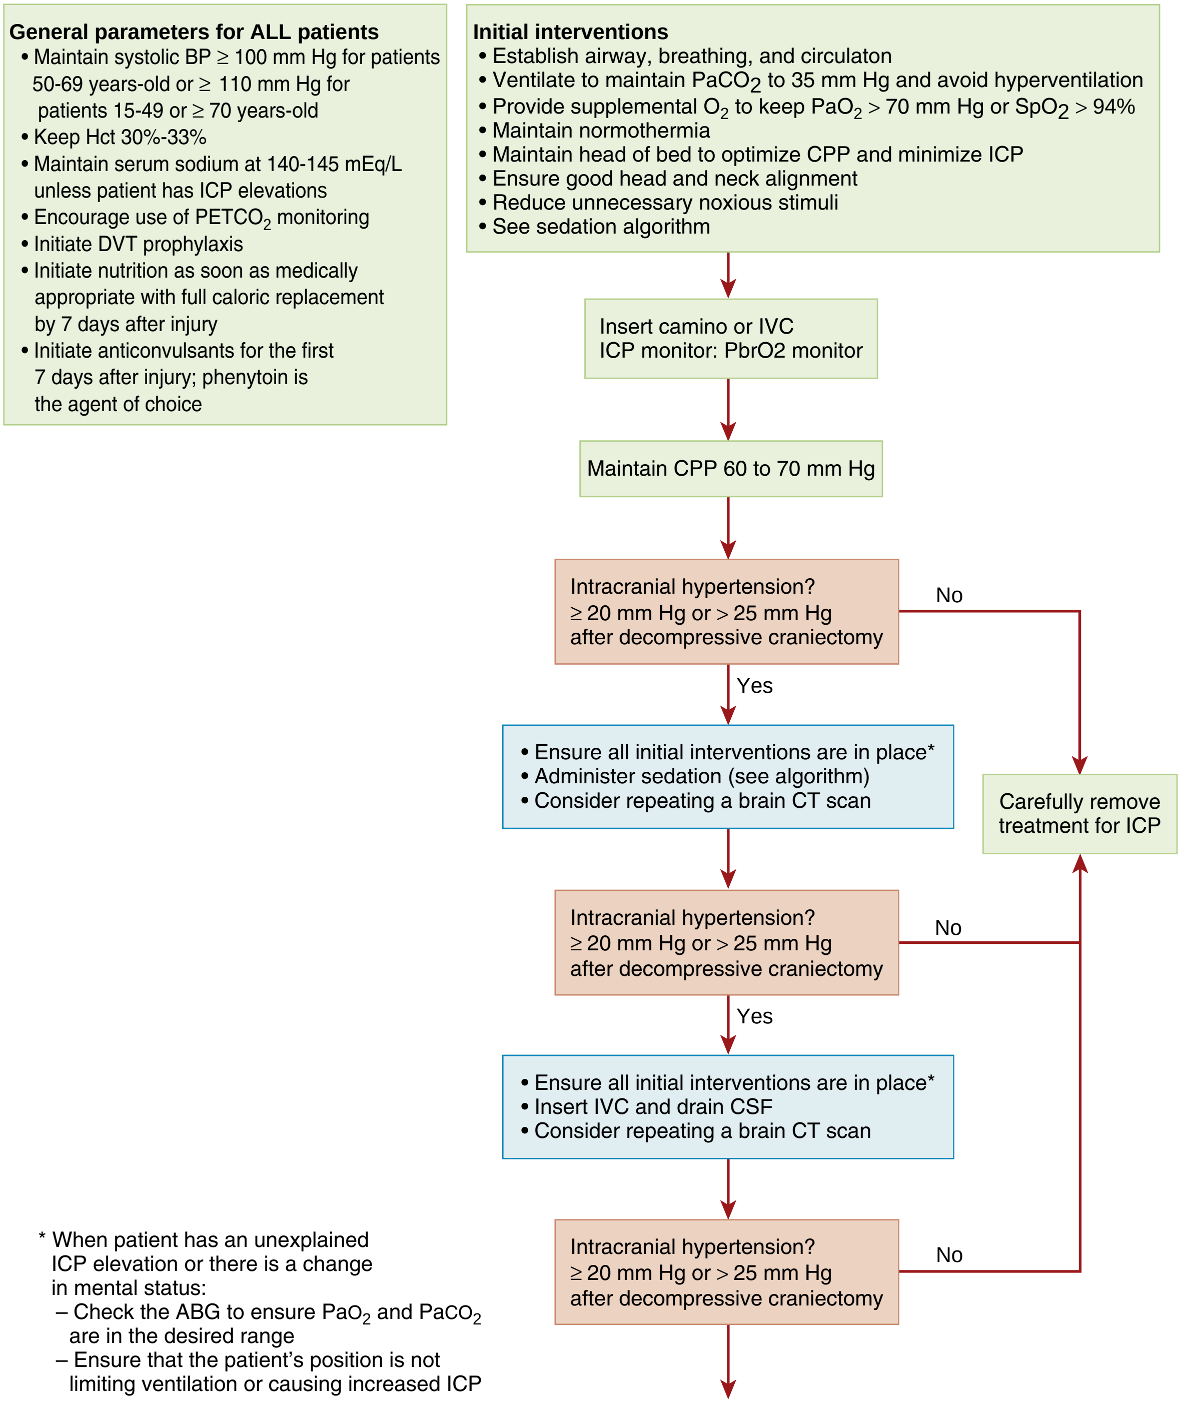
An active mechanical pump enables fluid administration rates up to 1500 mL/min
Compatible with crystalloid, colloid, packed red blood cells, washed salvaged blood, and plasma (*not* platelets)
Reservoir allows for mixing of products in preparation for rapid blood loss
Fluids infused at a controlled temperature (38°C-40°C)
Able to pump simultaneously through multiple intravenous lines
Fail-safe detection systems to prevent infusion of air
Accurate recording of fluid volume administered
Portable enough to travel with patient between units

Trauma produces shear forces that result in primary damage to neuronal cell bodies and axons, and to the vasculature. The pathophysiologic processes of secondary injury include metabolic failure, oxidative stress, and a cascade of biochemical and molecular events leading to both delayed necrotic and apoptotic cell death.[217] Secondary injury is often exacerbated by tissue hypoxia or ischemia and by inflammatory responses, and outcomes from TBI are influenced by a large number of interacting factors. Individual drugs such as free radical scavengers, antiinflammatory agents, and ion channel blockers have been effective in animals but have had little impact or yielded disappointing results in human trials. Long-term outcome cannot be predicted from TBI; thus full resuscitative efforts should be initiated and continued, even in the most severely injured. In a recent review of the Trauma Registry of the German Society for Trauma Patients looking at over 50,000 patients, outcome prediction was most accurate using the GCS motor score and pupil reactivity. In patients with bilateral fixed and dilated pupils, a good outcome was still seen in 8% of patients.[218]

Patients with mild TBI (GCS score of 13-15) who maintain a stable GCS score for 24 hours after injury are very unlikely to deteriorate further, although they are at risk for several postconcussive effects, including headache, memory loss, emotional lability (including aggressive behavior and violence), and sleep disturbance.[219] Moderate TBI (GCS score of 9-12) may be accompanied by intracranial lesions that require surgical evacuation, and early CT is strongly indicated. Early tracheal intubation, mechanical ventilation, and close observation may be required in the management of patients with moderate TBI because of combative or agitated behavior and the potentially catastrophic consequences of respiratory depression or pulmonary aspiration occurring during diagnostic evaluation. Extubation of the trachea can be undertaken if the patient is hemodynamically stable and appropriately responsive after the diagnostic workup. Treatment of secondary brain injury is accomplished by early correction and subsequent avoidance of hypoxia, prompt intravascular fluid resuscitation, and management of associated injuries. The timing of indicated noncranial surgery in these patients with moderate injury not requiring decompressive craniectomy is highly controversial because early surgery can increase the episodes of hypoxia and hypotension.[220]

Neurologic monitoring of patients with moderate TBI consists of serial assessment of consciousness and motor and sensory function (see also Chapter 39). Deterioration of the GCS score is an indication for urgent CT to establish the need for craniotomy or invasive monitoring of ICP. If frequent neurologic monitoring is not possible because of general anesthesia continuing longer than 2 hours, aggressive analgesia, or prophylaxis against delirium tremens, invasive ICP monitoring may be indicated.[162] Although mortality from moderate TBI is infrequent, many patients will have significant long-term morbidity.

Severe TBI is classified as a GCS score of 8 or less at the time of admission and carries a significant risk for mortality. Patients with severe TBI have mortality three times that of patients with other types of traumatic injury.[221] Early, rapid management focused on restoration of systemic homeostasis and perfusion-directed care of the injured brain will produce the best possible outcomes in this difficult population. Guidelines for all aspects of the management of patients with severe TBI have been published by the American Association of Neurological Surgeons and Brain Trauma Foundation, now in the fourth edition.[222] The clinical pathway in place at the R Adams Cowley Shock Trauma Center in Baltimore appears in Fig. 66.11.



General parameters for ALL patients

- Maintain systolic BP ≥ 100 mm Hg for patients 50-69 years-old or ≥ 110 mm Hg for patients 15-49 or ≥ 70 years-old
- Keep Hct 30%-33%
- Maintain serum sodium at 140-145 mEq/L unless patient has ICP elevations
- Encourage use of $PETCO_2$ monitoring
- Initiate DVT prophylaxis
- Initiate nutrition as soon as medically appropriate with full caloric replacement by 7 days after injury
- Initiate anticonvulsants for the first 7 days after injury; phenytoin is the agent of choice

Initial interventions

- Establish airway, breathing, and circulaton
- Ventilate to maintain $PaCO_2$ to 35 mm Hg and avoid hyperventilation
- Provide supplemental O_2 to keep $PaO_2 > 70$ mm Hg or $SpO_2 > 94\%$
- Maintain normothermia
- Maintain head of bed to optimize CPP and minimize ICP
- Ensure good head and neck alignment
- Reduce unnecessary noxious stimuli
- See sedation algorithm

Insert camino or IVC ICP monitor: PbrO2 monitor

Maintain CPP 60 to 70 mm Hg

Intracranial hypertension? ≥ 20 mm Hg or > 25 mm Hg after decompressive craniectomy

- Ensure all initial interventions are in place*
- Administer sedation (see algorithm)
- Consider repeating a brain CT scan

Intracranial hypertension? ≥ 20 mm Hg or > 25 mm Hg after decompressive craniectomy

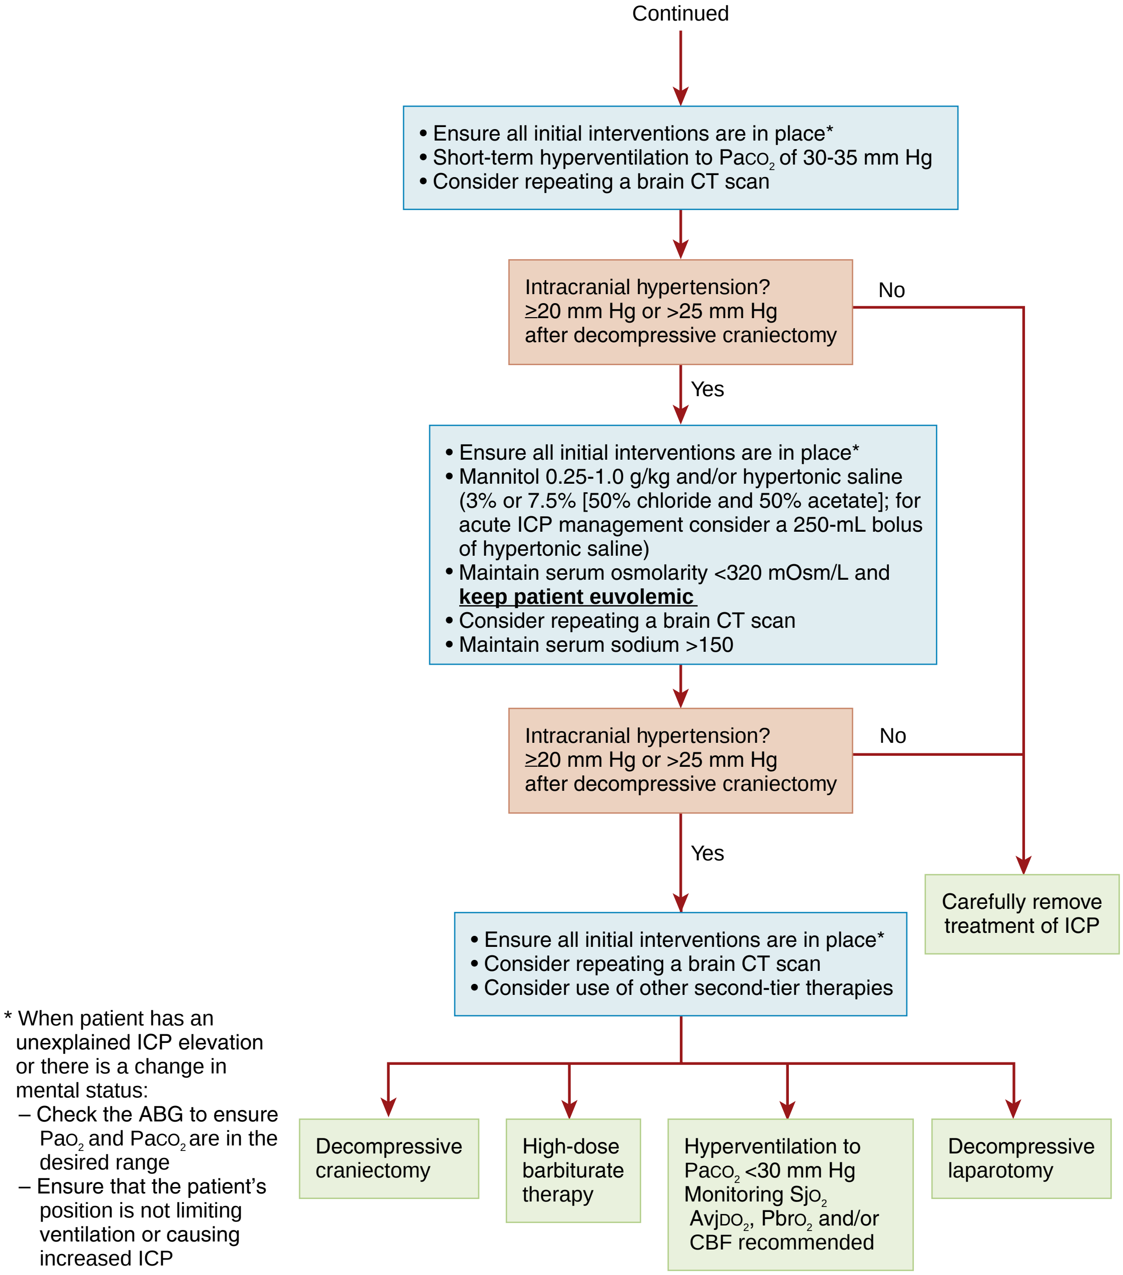
- Ensure all initial interventions are in place*
- Insert IVC and drain CSF
- Consider repeating a brain CT scan

Intracranial hypertension? ≥ 20 mm Hg or > 25 mm Hg after decompressive craniectomy

Carefully remove treatment for ICP

* When patient has an unexplained ICP elevation or there is a change in mental status:
– Check the ABG to ensure PaO_2 and $PaCO_2$ are in the desired range
– Ensure that the patient's position is not limiting ventilation or causing increased ICP

Fig. 66.11 Clinical pathway for management of severe traumatic brain injury. The goal of therapy is to maintain cerebral perfusion pressure 60 to 70 mm Hg by support of the circulation and control of intracranial pressure. Progressively more intensive therapies are added until this goal is achieved. *ABG,* Arterial blood gas; *BP,* blood pressure; *CBF,* cerebral blood flow; *CPP,* cerebral perfusion pressure; *CSF,* cerebrospinal fluid; *CT,* computed tomography; *DVT,* deep venous thrombosis; *Hct,* hematocrit; *ICP,* intracranial pressure; *IVC,* intraventricular catheter.



Continued
• Ensure all initial interventions are in place*
• Short-term hyperventilation to Paco$_2$ of 30-35 mm Hg
• Consider repeating a brain CT scan
Intracranial hypertension?
≥20 mm Hg or >25 mm Hg
after decompressive craniectomy
No
Yes
• Ensure all initial interventions are in place*
• Mannitol 0.25-1.0 g/kg and/or hypertonic saline (3% or 7.5% [50% chloride and 50% acetate]; for acute ICP management consider a 250-mL bolus of hypertonic saline)
• Maintain serum osmolarity <320 mOsm/L and keep patient euvolemic
• Consider repeating a brain CT scan
• Maintain serum sodium >150
Intracranial hypertension?

A single episode of hypoxemia ($PaO_2 < 60$ mm Hg) occurring in a patient with severe TBI can double the incidence of mortality.[223] Prehospital tracheal intubation, nonetheless, is controversial. Previously, intubation of the trachea before arriving at the hospital was advocated because providing a definitive airway allowed adequate oxygen to be delivered to the brain, benefiting the patients. Yet worsened neurologic outcomes have been described with attempts at prehospital tracheal intubation in adult trauma patients.[224,225] The first prospective trial of prehospital intubation, conducted in urban Australia, randomized patients with severe TBI—defined as evidence of head trauma and GCS of less than 9—to intubation by paramedics in the field or by physicians on the arrival to hospital.[226] Of 312 patients, the proportion with favorable outcome was 51% in the paramedic group, compared to 39% in the hospital tracheal intubation group ($P = .046$). Because no international standard or consensus exists, the patient should be transported as rapidly as possible to a facility capable of managing severe TBI or to the nearest facility capable of tracheal intubation of the patient and initiation of systemic resuscitation. The sine qua non is adequacy of systemic oxygenation, by whatever means this can best be accomplished.

The patient with TBI will frequently require perioperative monitoring to include ICP, brain temperature, arterial pressure, cerebral oxygenation, and other advanced monitoring techniques (see also Chapter 39). ICP may be monitored with an intraparenchymal probe or intraventricular catheter and should be maintained at less than 20 mm Hg. A variety of monitoring devices have been used to assess adequacy of cerebral oxygenation, including jugular venous oxygen saturation, positron emission tomography, near-infrared spectroscopy, and direct brain tissue oxygenation ($Pbto_2$) monitoring.[227] Brain tissue hypoxia may be corrected by increasing FiO_2, blood transfusion, inotropic support, or sedation, if increased ICP results in decreased cerebral blood flow.[228-231] Small studies suggest an improvement in Glasgow Outcome Score and mortality with brain oxygen–targeted strategies, but no overall consensus exists.

Finally, patients with severe TBI are also at risk for non-CNS organ failure. A retrospective review of patients with isolated TBI found a frequent incidence of subsequent organ failure: 89% developed dysfunction of at least one non-neurologic organ system. Takotsubo cardiomyopathy may develop in the setting of severe TBI and lead to severe myocardial dysfunction in the patient with brain injury.[232] The reasons for development include interplay between the neuroendocrine system and the injured brain. A catecholamine surge that occurs after TBI may manifest as subendocardial ischemia, leading to biventricular heart failure, even in young, previously healthy patients. This cycle may be exacerbated during OR procedures when vasoactive drugs might be administered. β-Adrenergic blockade may be protective in human studies in patients with brain injuries. Retrospective database reviews have indicated improved neurologic outcome and reduced morbidity and mortality in patients receiving peri-injury β-adrenergic blockade although the quality of evidence is not high.[233-236]

TRAUMATIC BRAIN INJURY AND CONCOMITANT TRAUMA

Patients with isolated head injuries can be managed with traditional ventilatory strategies, but those with chest trauma, aspiration, or massive resuscitation after shock are at high risk for the development of ARDS. The classic teaching of no or low-level positive end-expiratory pressure (PEEP) to prevent increased ICP is inappropriate because hypoxemia may not be corrected. With adequate intravascular volume resuscitation, PEEP does not increase ICP or decrease cerebral perfusion pressure (CPP)[237] and may actually decrease ICP as a result of improved cerebral oxygenation.[238] Patients who develop ARDS after TBI are at risk for cerebral hypoxia.[239] A double-hit model has been proposed as the cause of ARDS secondary to CNS trauma—severe TBI leads to a systemic inflammatory response, which then primes the lungs to be more susceptible to injurious ventilator strategies or other mediators of lung injury. ARDS and cardiac insufficiency after TBI may lead to compromised systemic oxygenation and therefore a decrease in cerebral oxygen delivery.[240] Hyperventilation therapy (e.g., at a $PaCO_2$ of 25 mm Hg), long a mainstay in the management of patients with TBI, is no longer recommended as a prophylactic treatment. A range of $PaCO_2$ between 30 and 35 mm Hg should be induced with hyperventilation to 30 mm Hg only for episodes of increased ICP that cannot be controlled with sedatives, drainage of cerebrospinal fluid, neuromuscular blockade, osmotic drugs, or barbiturate coma.[161] Hyperventilation during the first 24 hours is of concern because of the critical reductions in perfusion during this timeframe. However, these recommendations should be taken in context and modified in the face of unstable clinical circumstances such as an expanding mass lesion or signs of imminent herniation.[241]

The most challenging of all trauma patients are those with severe TBI and coexisting hemorrhagic shock. A single episode of hypotension, defined as systolic blood pressure lower than 90 mm Hg, is associated with an increase in morbidity and doubled mortality after severe TBI.[242] Hypotension together with hypoxia increases mortality 30-fold. Current recommendations are to maintain a patient with severe TBI in a euvolemic state. Therefore *fluid resuscitation is the mainstay of therapy,* followed by vasoactive infusions as needed. The ideal fluid has not been defined, but perhaps hypertonic saline solutions are optimal. Correction of anemia from acute blood loss is the priority; however, an optimal target hematocrit has not been defined. Animal models and healthy human subjects support maintaining a hemoglobin lower than 7 g/dL because impaired brain function may occur with lower values, yet a hemoglobin lower than 10 g/dL may be detrimental to recovery from TBI.[243] At this time it is not clear what optimal transfusion trigger should be used (see also Chapter 49). After the initial ABCDE management of a patient with severe TBI, a stepwise approach to maintenance of CPP is initiated, with a currently recommended goal range of 60 to 70 mm Hg, as discussed in Chapter 57.

Decompressive craniectomy is a surgical procedure used to control severely increased ICP and prevent herniation after stroke, and it is now used for the same indications after severe TBI.[244] Decompressive craniectomy is indicated for selected anatomic patterns of TBI, such as when CPP cannot be maintained despite vigorous application of the previously described therapies, including barbiturate coma. Relieving ICP by removal of a piece of cranium and use of a dural patch may improve mortality and morbidity in patients who might not otherwise survive.[245] Decompressive laparotomy may be indicated in patients with severe TBI if coexisting injuries or vigorous intravascular volume infusion have increased intraabdominal compartment pressure to greater than 20 mm Hg. Increased abdominal pressure worsens pulmonary mechanics, thus necessitating higher MAP to maintain arterial oxygen saturation. This increase in ventilating pressure will increase intrathoracic pressure and impair venous drainage from the head and consequently decrease CPP. The use of decompressive celiotomy as a therapy to reduce ICP has been described[246] for managing patients with severe TBI and a potential multiple compartment syndrome.[247] Fluid therapy, ARDS, or both may increase intraabdominal pressure and intrathoracic pressure, thereby increasing ICP. Further fluid administration to support cerebral perfusion or increasing ventilatory support to treat ARDS further exacerbates this problem. This can create a cycle that ultimately produces multiple compartment syndrome and necessitates opening of the abdomen, even in the absence of primary abdominal trauma. Isolated TBI can thus become a multisystem disease.

Like hyperventilation therapy, the use of hypothermia to treat severe TBI has changed. Early studies demonstrated that moderate, systemic hypothermia reduces both the rate of cerebral edema and mortality after cortical injury in laboratory animals.[248,249] Small clinical series in humans also suggested improved outcome in patients with TBI when hypothermia was maintained for 24 or 48 hours.[250,251] However, a multicenter, randomized trial of hypothermia (33°C) versus normothermia demonstrated no improvement in outcome in a population of patients with severe TBI.[252] Patients who were hypothermic on admission and then were randomized to the normothermia group had a worse outcome than those who were left hypothermic, thus leading to the recommendation that patients with severe TBI who are hypothermic on admission not undergo active rewarming. Current Brain Trauma Foundation guidelines do not recommend early, short-term, prophylactic hypothermia.[222]

MANAGEMENT OF INTRACRANIAL PRESSURE IN THE OPERATING ROOM

Although most interventions for management of a patient with severe TBI will occur in the ICU, urgent cranial or noncranial surgery can be indicated. The previously described therapies should be continued throughout the perioperative period, including positional therapy (when possible), aggressive hemodynamic monitoring and resuscitation, administration of osmotic agents (with attention to maintaining euvolemia), and deep levels of analgesia and sedation. Appropriate anesthetic choices include opioids and low concentrations of volatile anesthetics. Pharmacologic management of TBI is the mainstay of the anesthesiologist's role in the OR. Intraoperative management of elevated ICP may be accomplished with osmotic diuretics or hypertonic saline. No difference was noted in long-term outcomes between mannitol and hypertonic saline on outcomes at 6 months, although hypertonic saline may potentiate small short-term improvements in cerebral blood flow and CPP.[253,254] A meta-analysis of common drugs used in intraoperative management of patients with TBI, including propofol, barbiturates, opioids, benzodiazepines, and corticosteroids, showed corticosteroids to be the only drug associated with an increase in mortality. The other drugs had acute benefit in reductions in ICP and sedation, but no appreciable long-term benefit.[219,222]

SPINAL CORD INJURY

SCI after trauma affects some 13,000 Americans each year.[216] Blunt trauma accounts for most of SCI: 36% from motor vehicle collisions and 42% from falls with only 4% from firearms. Cervical spine injuries occur in 1.5% to 3% of all major trauma. Over 50% of SCIs involve the cervical spine, usually between the C4 and C7 levels. Complete quadriplegia occurs in 11% of SCI cases. It is important to realize that more than 40% of trauma patients who have SCI may also have other significant injuries, including TBI.

Most spinal injuries are in the lower cervical spine, just above the thorax, or in the upper lumbar region, just below the thorax. Blunt SCI is most common in the regions of the cord that are most flexible, especially at the junctions between flexible and inflexible segments. The vertebral column is divided longitudinally into three columns: anterior, middle, and posterior; injuries to any two of these three columns suggest biomechanical instability. These are the patients who will often require urgent surgical stabilization. Patients with unstable cervical spine injuries who meet criteria for emergency intubation should undergo rapid sequence induction (see section above on protection of the cervical spine). SCI at midthoracic levels is less common because of the rotational stabilization provided by the rib cage and intercostal musculature.

SCI is commonly accompanied by radiographically visible injury to the bony spine and concomitant disruption of the muscles, ligaments, and soft tissues that support it. However, clinically significant injury to the cervical spinal cord can occur in the absence of visible skeletal injury. This entity, known as SCI without radiographic abnormality (SCIWORA), is more common in children and is presumably the result of temporary hyperdistraction or torsion of the neck insufficient to disrupt the bony skeleton.[255]

Primary injury to the spinal cord sustained at the time of injury may be exacerbated by secondary factors (Fig. 66.12). The combination of biochemical changes, vascular disruption, and electrolyte abnormalities can lead to cellular changes and worsening of SCI lesions up to 3 days after injury.[256] SCI includes sensory deficits, motor deficits, and both. Incomplete deficits may be worse on one side than the other and may improve rapidly in the first minutes after injury. Complete deficits—representing total disruption of the spinal cord at one level—are much more ominous, with generally little improvement seen over time. Spine injuries above the level of T4 to T6 are accompanied by significant hypotension because of inappropriate vasodilatation, loss of cardiac inotropy, and bradycardia resulting from denervation of the cardiac accelerator fibers (neurogenic shock). (Note the distinction between *neurogenic shock* and the incorrect term *spinal shock*, which refers to a loss of reflexes.) Functioning of the lower cord will gradually return, along with restoration of normal vascular tone. Diagnosing cervical spine instability can be difficult. The Eastern Association for the Surgery of Trauma has published guidelines regarding which patients require cervical spine radiographs, which views and studies should be obtained, and how to determine the absence of significant ligamentous injury in an obtunded patient.[257] For the obtunded patient, a high-quality CT scan without evidence of cervical SCI is considered to be adequate for clearance although this is not universally accepted. Many institutions still require magnetic resonance imaging to rule out ligamentous injury in this patient population. The most commonly missed cervical fractures are at the C1 to C2 and C7 to T1 levels, usually the result of inadequate imaging.

Early intubation of the trachea is almost universally required for patients with cervical spine fracture and quadriplegia. Ventilatory support is almost always required for patients with a deficit above C4, because they will lack sufficient diaphragmatic function. Patients

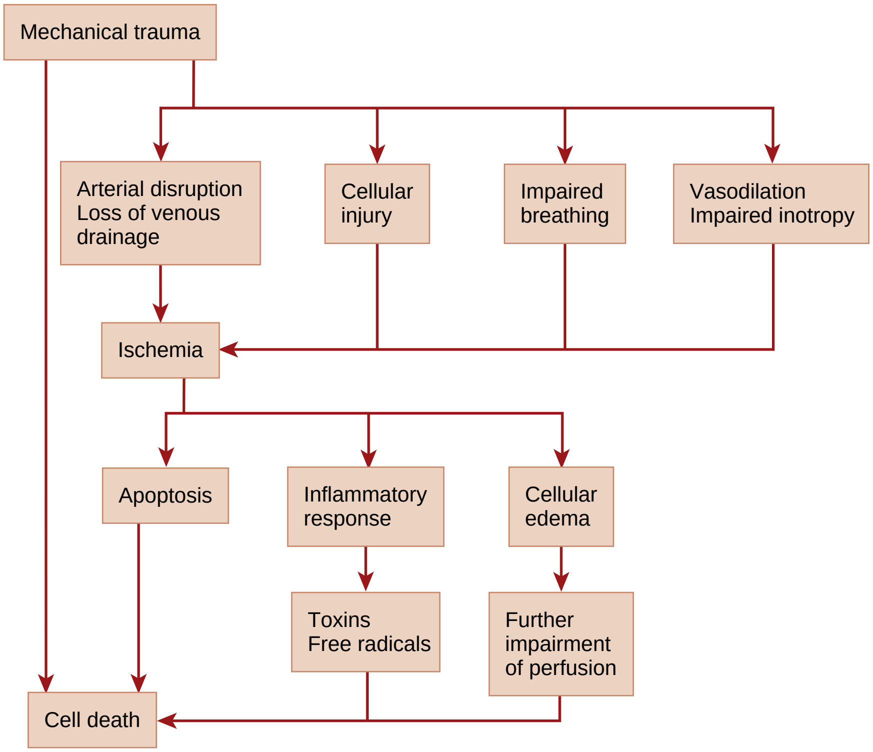

Fig. 66.12 Mechanisms of spinal cord injury. Mechanical trauma to the spinal cord is exacerbated by systemic hypoperfusion or hypoxia. (Reprinted with permission from Dutton RP. Spinal cord injury. *Int Anesthesiol Clin.* 2002;40:109.)

with levels from C6 to C7 may need support because of impairment in respiratory muscle function resulting from (1) loss of chest wall innervation, (2) paradoxical respiratory motion, (3) inability to clear secretions, and (4) decreased lung and chest wall compliance. Early tracheal intubation is recommended and, if elective, often can be accomplished by awake fiberoptic bronchoscopy or video laryngoscopy before hypoxia renders the patient anxious and uncooperative.[258,259] Also, two retrospective studies have evaluated the need for tracheal intubation in patients with cervical SCI. Como and colleagues[258] identified 119 patients, 45 of whom had complete SCI. All patients with injuries at C5 and above required intubation, and 71% of these progressed to tracheostomy. A second study of 178 patients with complete cervical SCI showed 70% of patients required tracheostomy, particularly those with an injury between C4 and C7.[259] Spontaneous ventilation and extubation of the trachea are possible after surgical stabilization and resolution of neurogenic shock, although pneumonia is a common and recurrent complication that frequently necessitates tracheostomy to facilitate pulmonary toilet.[260]

Although administration of a glucocorticoid steroid bolus in patients with blunt SCI and deficit was recommended, current guidelines suggest caution. Large-dose glucocorticoid therapy has resulted in a small, but statistically significant, improvement in neurologic level after SCI in two large multicenter trials: National Acute Spinal Cord Injury Study (NASCIS) II and III.[261,262] However, the NASCIS results have been challenged for several reasons.[263-265] The positive benefits seen with high-dose steroid administration were driven by results in a few subpopulations and were not present in a majority of patients. The improvement in spinal level seen after steroid administration has not been shown to lead to increased survival or improved quality of life, and the results have not been reproducible in other studies of acute SCI. Current recommendations by the American Association of Neurological Surgeons and the Congress of Neurological Surgeons state that there is no consistent or compelling medical evidence to justify the use of methylprednisolone for acute SCI.[266]

INTRAOPERATIVE MANAGEMENT OF SPINAL CORD INJURY

A patient about to undergo surgical reduction and fixation of a spinal column fracture presents challenges for the anesthesiologist. First and foremost is the need for intubation of the trachea in a patient with a known injury to the cervical spine. Direct laryngoscopy with in-line stabilization is appropriate in the emergency setting and in unconscious, combative, or hypoxemic patients when the status of the spine is not known.[267] Tracheal intubation can occur in the OR, in an awake, alert, and cooperative patient by several methods known to produce less displacement of the cervical spine, presumably with less risk for worsening an unstable SCI. A common technique in current clinical practice is awake fiberoptic intubation. Although the nasal route is associated with an easier path to intubation in most patients, it can lead to an increased risk for sinusitis in the ICU if the trachea is not extubated at the end of the procedure. Oral intubation may be more challenging technically but will be of greater value if the patient remains mechanically ventilated. Blind nasal intubation, transillumination with a lighted stylet, and use of an intubating LMA, videolaryngoscopy, or any of a variety of other instrument systems for indirect laryngoscopy are acceptable. Again, in comparative studies of direct laryngoscopy, videolaryngoscopy, fiberoptic examination, blind nasal intubation, or cricothyrotomy in patients with known cervical cord or spine injuries, no difference is seen in neurologic deterioration with technique used and no clear evidence exists that direct laryngoscopy worsens outcome. Clinicians are advised to use the equipment and techniques with which they are most familiar. The important concept is to successfully achieve tracheal intubation while minimizing motion of the cervical spine and preserving the ability to assess neurologic function after positioning.[68]

A patient with a partial deficit and visible spinal canal impingement on imaging studies is considered an emergency because of the potential for regaining neurologic function after decompression. Timing for surgery suggests that earlier decompression may improve outcomes in some patients, particularly those with cervical injuries, although the exact timing remains controversial.[268,269] Hemodynamic instability may complicate urgent and emergent spinal surgery. Hypotension from neurogenic shock is characterized by an inappropriate bradycardia resulting from loss of cardiac accelerator function and unopposed parasympathetic tone. However, this situation can be difficult to distinguish from hypotension resulting from acute hemorrhage, and a trial of fluid administration is still indicated, subject to the end points of resuscitation listed earlier. Once hemorrhage has been controlled or ruled out, patients who have maintenance of an increased MAP more than 85 mm Hg for 7 days after SCI may have improved functional recovery. This approach is highly controversial but remains a recommendation in treatment according to published guidelines.[270]

Orthopedic and Soft Tissue Trauma

Musculoskeletal injuries are the most frequent indication for operative management in most trauma centers (see also Chapter 64). Orthopedic trauma, like TBIs and SCIs, can be associated with long-term pain and disability. In addition to physical handicaps that these patients may endure, orthopedic injuries incurred in both civilian and military settings lead to long-term psychological trauma.[271-273] The length of many procedures, particularly in patients with multiple extremity injuries, necessitates attention to body positioning, maintenance of normothermia, fluid balance, and preservation of peripheral blood flow.

Timing of operative intervention in polytrauma patients with orthopedic injuries has been a topic of considerable academic and clinical discussion. Musculoskeletal injuries represent common injury patterns seen in patients with high-energy mechanisms of injury and are one of the more common reasons for operative intervention in the trauma population.[274,275] Historically, injuries to the extremities in multisystem trauma patients who were too critically injured for definitive operative intervention were managed with traction and prolonged immobilization. These patients experienced high rates of pulmonary failure and prolonged mechanical ventilation, developed sepsis frequently, and had high mortality rates.[276] Specifically, pulmonary complications have been a common occurrence in this population of trauma patients with nearly 30% of patients with multiple extremity injuries experiencing pulmonary morbidity. Therefore the goal of fracture management in the multisystem trauma patient revolves around restoring musculoskeletal anatomy that allows for mobilization, pulmonary toilet, and adequate pain control.

In the patient with isolated extremity or hip fracture without polytrauma, the evidence remains clear that early definitive fracture care improves outcomes. In hip fracture patients, current U.S.[277] and Canadian[278] guidelines recommend surgery within 48 hours. Within the United Kingdom, surgery within 36 hours is a quality-of-care indicator although adherence to these guidelines is incomplete.[279] These recommendations may require revision as more recent work has consistently demonstrated an increasing complication rate for surgical procedures performed over 24 hours after injury.[280-283] In the most recent study looking at the association between wait time and 30-day mortality, Pincus and associates examined the impact of wait time in hours on mortality and other complications including myocardial infarction, deep vein thrombosis, pulmonary embolism, and pneumonia.[284] Among adults requiring hip fracture surgery, a wait time of 24 hours appears to be a threshold defining higher risk. The study population, however, did not include many patients with significant trauma (<1% of patients had an ISS ≥16) or multiple fractures (4.9%) making it impossible to directly apply these results to the polytrauma patient. Similarly, fixation of femur fractures in patients with a lower ISS within 48 hours of injury is also associated with improved outcomes.[285]

SPECIFIC ORTHOPEDIC CONDITIONS

Hip fracture is a common, morbid, and costly event among older adults. Frequently, patients with isolated hip fracture present to the OR for urgent repair. Regional anesthesia is associated with decreased odds of inpatient mortality and pulmonary complications among patients with hip fracture in contrast to general anesthesia.[286] A retrospective cohort of 18,158 patients undergoing surgery for hip fracture in 126 hospitals showed that 5254 (29%) received regional anesthesia. Although unadjusted rates of mortality and cardiovascular complications did not differ by anesthesia type, regional anesthesia was associated with decreased adjusted odds of mortality (odds ratio: .710, 95% confidence interval [CI] .541, .932, $P = .014$) and pulmonary complications (odds ratio: .752, 95% CI .637, 0.887, $P < .0001$) relative to general anesthesia.[287]

Dislocation of the hip is common after high-energy trauma and is frequently accompanied by fracture of the acetabulum. Whereas the fracture itself can be safely managed on a delayed basis or nonoperatively, the dislocation is a medical emergency that must be promptly addressed if the patient is to have a good functional outcome. Failure to promptly diagnose and reduce a dislocated hip joint is a significant risk factor for avascular necrosis of the femoral head. Reduction typically requires a very deep level of sedation, which may be facilitated by nondepolarizing neuromuscular blockade. For this reason, the anesthesiologist is commonly involved.[288] Although a dislocated hip can be reduced in a spontaneously breathing sedated patient, an acutely injured patient is at high risk for aspiration of gastric contents. Any patient who will be undergoing surgery soon (such as for an open long-bone fracture or exploratory laparotomy) can be tracheally intubated at the time of reduction and maintained with appropriate sedation and analgesia until reaching the OR. Other patients who may require intubation even for uncomplicated reductions include those who are inebriated or uncooperative, hemodynamically unstable, or suffering from pulmonary dysfunction. Additionally, successful postoperative fracture reduction is more difficult to achieve in morbidly obese patients than in those with normal body mass index.[289]

Unlike acetabular fractures, fracture of the pelvic ring requires immediate recognition and management by the trauma team. Hemorrhage, even exsanguination, is common after a major pelvic ring fracture and is a leading contributor to early death after motor vehicle collisions. Bleeding occurs from multiply disrupted venous beds in the posterior pelvic bowl; if the pelvis is unstable, no anatomic barrier exists to continued expansion of this retroperitoneal bleeding. Surgical exploration by way of the peritoneum is usually unrewarding because the bleeding vessels are not easily accessed.[290] In the past, therapy consisted of supportive volume resuscitation, external fixation of the unstable pelvis, and angiography. Despite this multidisciplinary approach, mortality remained frequent in these patients, partially because of the inability of angioembolization to control venous bleeding from the rich venous plexuses associated with the most severe fractures. The technique of preperitoneal packing has been adopted by many U.S. trauma centers. Preperitoneal packing via laparotomy is a rapid method for controlling pelvic fracture–related hemorrhage that can supplant the need for emergent angiography and reduces transfusion requirements and mortality.[291] Endotracheal intubation is usually undertaken on an emergency basis in a hypotensive patient, and the anesthesiologist may remain with the patient throughout the initial hours of stabilization to manage sedation, analgesia, transport, and ongoing resuscitation needs. In the absence of an orthopedic specialist, temporary stabilization and tamponade of some pelvic fractures can be accomplished with use of a specially made pelvic binder, the pelvic portion of military antishock trousers, or a bed sheet knotted tightly around the bony pelvis.[292] Mechanically unstable pelvic ring fractures are associated with increased fluid and blood resuscitation volumes, significantly more frequent presence of concomitant injuries, and increased ventilation and ICU stay, rate of MODS, sepsis, and rate of mortality.[293]

Patients with pelvic fractures can initially be divided into two groups: (1) stable pelvic fracture; or (2) displaced pelvic ring fractures with hemodynamic instability or high risk for deterioration. This second group has the highest risk for complications and mortality related to their injuries. The presence of associated injuries to the head, chest, and abdomen can lead to conflicting priorities in management of these patients. For example, a CT finding of a high-grade splenic injury in the setting of a severe pelvic injury and hemodynamic instability may require an exploratory laparotomy before addressing the pelvic injury. These patients may present for operative procedures with or without early interventions such as placement of a pelvic binder or resuscitative endovascular balloon occlusion of the aorta. As the unstable trauma patient is moved to the angiography suite or hybrid OR, resuscitation should continue to maintain an acceptable perfusion pressure; and survival is higher if this transition occurs within 3 hours of presentation.[294] Management of these interventions in the OR requires an understanding of the anatomy, physiology, and surgical considerations involved in their employment in the operative setting as discussed above.

Open fractures should be pulse-lavaged and debrided as soon as possible after injury to minimize the risk for infectious complications. If ongoing resuscitation or unstable TBI precludes the patient from early management in the OR, this procedure can be performed at the bedside. Despite the frequency of open fractures, their management remains one of the greatest and most debated orthopedic challenges. Timing of surgical fixation in open fractures is often surgeon-specific or center-specific, because little consensus exists among orthopedic surgeons as to optimal treatment.[295]

The advantages and disadvantages of regional and general anesthesia are summarized in Boxes 66.9 and 66.10. Regional anesthesia seems to decrease postoperative morbidity and mortality[287,296,297] (including cognitive measures of function), but clinically measurable benefits may not be seen in patients receiving combined general and regional techniques.[298-300] One other prevalent concern in the management of an orthopedic trauma patient is the concomitant use of regional anesthesia, analgesia, or both and prophylaxis for venous thromboembolism, as discussed in Chapter 64.

Intraoperative TEE has shown that most patients undergoing long-bone fracture manipulation experience microembolism of fat and marrow.[301] Most patients suffer no discernible clinical impact from this phenomenon, but some will experience a significant acute inflammatory response. After long bone fractures, some lung dysfunction occurs in almost all patients, ranging from minor laboratory abnormalities to full blown fat embolism syndrome (FES). A lack of universally

BOX 66.9 Advantages and Disadvantages of Regional Anesthesia for Trauma

Advantages

Allows continued assessment of mental status
Increased vascular flow
Avoidance of airway instrumentation
Improved postoperative mental status
Decreased blood loss
Decreased incidence of deep venous thrombosis
Improved postoperative analgesia
Better pulmonary toilet
Earlier mobilization
Lower incidence of long-term pain syndromes

Disadvantages

Peripheral nerve function difficult to assess
Patient refusal common
Requirement for sedation
Hemodynamic instability with placement
Longer time to achieve anesthesia
Not suitable for multiple body regions
May wear off before procedure(s) conclude(s)

BOX 66.10 Advantages and Disadvantages of General Anesthesia for Trauma Patients

Advantages

Speed of onset
Duration: can be maintained as long as needed
Allows multiple procedures for multiple injuries
Greater patient acceptance
Allows positive-pressure ventilation

Disadvantages

Impairment of global neurologic examination
Requirement for airway instrumentation
Hemodynamic management more complex

BOX 66.11 Risk Factors for the Development of Compartment Syndrome

Orthopedic

Fractures and operative repair

Vascular

Reperfusion injury
Hemorrhage with hematoma formation
Ischemia from arterial and venous injuries

Soft Tissue

Crush injury
Burns
Prolonged compression in immobile state

Iatrogenic

Casts and circular dressing
Use of pneumatic antishock garment
Intraosseous fluid replacement in infant or child
Pulsatile lavage with extravasation
Extravasation from venous or arterial puncture site

Miscellaneous

Snakebite
Acute exertion

accepted diagnostic criteria combined with concomitant pulmonary and cardiovascular dysfunction accounts for the varying incidence reported in the literature. Clinically significant FES occurs in 3% to 10% of patients but is likely underdiagnosed in patients with multiple injuries or a high ISS.[302] Patients with coexisting lung injury are at additional risk for FES. Signs include hypoxia, tachycardia, mental status changes, and, classically, a petechial rash on the axillae, upper arms and shoulders, chest, neck, and conjunctivae. FES should be considered whenever the alveolar-arterial oxygen gradient deteriorates in conjunction with decreased pulmonary compliance and CNS deterioration. Under general anesthesia, the CNS changes will not be apparent but may be manifested as failure to awaken after surgery. If central hemodynamic monitoring is available, pulmonary artery pressure is elevated, often accompanied by decreases in the cardiac index. Diagnosis in the OR is largely based on the clinical findings after ruling out other causes of hypoxemia. Fat globules in urine are nondiagnostic, but lung infiltrates seen on chest radiography confirm the presence of lung injury and the need for appropriate ventilatory management with oxygen, higher PEEP, and possible longer-term mechanical ventilatory support.[303,304] Treatment includes early recognition, administration of oxygen, and judicious fluid management.[305] A change in the orthopedic procedure may be indicated, such as converting intramedullary nailing of the femur to external fixation. In the patient with bilateral femur fractures, it has been proposed that 1 to 2 days be allowed to pass between successive nailing procedures.[306]

Acute compartment syndrome of the extremities is defined as a “condition in which increased pressure within a limited space compromises the circulation and function of the tissues within that space.”[307] The most common cause of compartment syndrome is edema secondary to muscle injury and associated hematoma formation. Although most commonly associated with traumatic injuries, compartment syndrome also can occur because of causes associated with trauma, including reperfusion injury, burns, drug overdose, and prolonged limb compression (Box 66.11). The most common fractures associated with the development of compartment syndrome are those of the tibial shaft (40%) and forearm (18%).[308,309] Forearm compartment syndrome requiring fasciotomy predominantly affects males and can occur after either a fracture or soft-tissue injury. A further 23% of cases are caused by soft-tissue injuries without fracture.[310] Although no randomized, prospective trials have been conducted, regional anesthesia does not blunt detection of compartment syndromes if there is not an associated dense motor block.[311]

Fasciotomy is usually indicated when compartment pressure approaches 20 to 30 mm Hg below diastolic pressure in any patient with a worsening clinical condition, a documented rising tissue pressure, major soft tissue injury, or a history of 4 to 6 hours of total ischemia of an extremity. Prophylactic fasciotomy may be indicated in patients with warm ischemic time more than 2 hours, ligation of the major veins in the popliteal region or distal part of the thigh, and crush injuries. Early or prophylactic fasciotomy decreases subsequent muscle loss.[312]

Crush syndrome is the general manifestation of crush injury caused by continuous prolonged pressure on one or more extremities[313] and is commonly found in patients who have been trapped in one position for an extended period. Muscle injury secondary to ischemia causes myoglobinuria, which can lead to acute renal failure and subsequent profound electrolyte disturbances. The most critical treatment consists of crystalloid fluid resuscitation; a total body fluid deficit of 15 L may occur in severe rhabdomyolysis.[314] Osmotic diuresis with mannitol and alkalization of urine with sodium bicarbonate to prevent precipitation of myoglobin in the renal tubules are controversial.[315] The preferred therapy for renal failure secondary to rhabdomyolysis at the shock trauma center is continuous renal replacement therapy and hemofiltration.[316] Most of these patients eventually have full recovery of native renal function.[317]

SOFT TISSUE TRAUMA

Assessment of soft tissue injury is critical in the management of a trauma patient. Muscular coverage is necessary for the viability of any orthopedic repair, but it may be jeopardized by avulsion at the time of injury, ischemia from elevated compartment pressure, and ongoing bacterial infection in open wounds. Acute surgical management of soft tissue injury is straightforward: all dead or devitalized tissue must be debrided, and the wound thoroughly irrigated to reduce the load of bacterial contaminants. When muscle or fascia involvement is significant, serial debridement at frequent intervals is necessary to establish a margin of completely viable tissue. Vacuum dressings for large soft tissue wounds are gaining in popularity because continuous negative pressure over the wound surface removes contaminants and encourages blood flow.[318] When serial debridement establishes viable tissue at all margins of the wound, arrangements for definitive closure can be made. Closure may be as simple as a split-thickness skin graft or as complex as free tissue transfer of muscle and fascia from an uninjured portion of the body, with attendant arterial and venous anastomoses.

A degloving injury results in significant soft tissue loss, usually in the extremities. Multiple plastic surgery and reconstructive procedures may be necessary. General anesthesia is usually required, although combining it with epidural or regional block analgesia may confer the benefits of both techniques. Close consultation with the surgical teams is suggested.

Superficial vacuum dressings can be changed at the bedside under light sedation, but patients with deep wound dressings may require general anesthesia. The need for repeated surgeries is an important consideration for the anesthetic technique. Anesthesia for free tissue transfer surgery requires meticulous attention to detail because these operations can be quite protracted. Every effort should be made to facilitate perfusion of the grafted vessels, including keeping the patient warm, euvolemic, and comfortable, and maintaining the hematocrit in the rheologically favorable range of 25% to 30%. The use of epidural anesthesia and analgesia is controversial, with some surgeons favoring it for its vasodilatory effects and others being concerned that it will induce a steal phenomenon that will actually limit flow in the denervated free tissue.[319] The use of vasopressors in microsurgery is generally avoided. Yet in one study, the vasopressor used did not cause more complications.[320]

Other Traumatic Injuries

HEAD AND NECK SURGERY

Except for emergency exploration of penetrating trauma to zone II of the neck (from the clavicles up to the angle of the mandible), most surgical repair of head and neck trauma will occur in the subacute phase, after complete resuscitation and secondary diagnostic studies. Anesthetic management of these patients is not substantially different from that for similar elective procedures, although coexisting injuries may influence patient positioning, airway management, and ventilator settings.[321,322] Surgery on the mandible and maxilla will be facilitated by nasotracheal intubation, but a secure airway should be not jeopardized by attempting to switch from an oral to a nasal tube in a patient in whom visualization of the larynx might be difficult because of traumatic swelling or body habitus. It is safer in these cases for the surgeon to either work around an oral tube secured behind the second molar (to allow dental occlusion) or place a tracheostomy if the need for intubation and mechanical ventilation is likely to be protracted. Surgery on the zygoma and the nasal, orbital, and ethmoid bones will be possible with an oral ETT. Securing the ETT to the molar with a fine-gauge wire will help stabilize it through the operation. All of these surgeries will lead to significant soft tissue swelling in the immediate postoperative period, often necessitating several days of continued intubation and sedation until sufficient venous drainage has occurred to allow safe extubation of the trachea. Though not by itself definitive, the presence of an air leak when the ETT cuff is deflated is suggestive that the airway will remain patent once the tube is removed.

CHEST INJURIES: PULMONARY

Injuries to the lung parenchyma that produce pneumothorax can be managed by tube thoracostomy to relieve tension, drain accumulated blood, and apply suction to the pleural space until the air leak spontaneously resolves. Bleeding from the low-pressure pulmonary circulation is usually self-limited. Thoracostomy is uncommon but becomes necessary when evidence exists of mediastinal injury, chest tube output exceeds 1500 mL in the first hours after injury, tracheal or bronchial injury and massive air leak are apparent, or the patient is hemodynamically unstable with evident thoracic pathology.[33] Blood collected from the pleural space is generally free of clotting factors and can be directly reinfused with any of several commercial systems[323]; however, concern has been expressed that this may be prothrombotic and potentially harmful.[324] Hemorrhage necessitating surgery may be from injured intercostal or internal mammary arteries or from the lung parenchyma. Staple resection of injured lung or even anatomic lobectomy is not uncommon, particularly after penetrating trauma.

Although double-lumen endotracheal intubation is desirable during urgent thoracotomy, this should not be the initial approach. Rapid sequence induction with a large-caliber (at least 8.0 mm in internal diameter) conventional ETT will allow diagnostic bronchoscopy if needed. The change to a double-lumen tube can then be made under controlled conditions in the presence of adequate oxygenation, anesthesia, and muscle relaxation. Tolerance of single-lung ventilation is variable in the trauma population and depends in large part on the absence of significant pathologic findings in the ventilated lung. Many patients with blunt thoracic injury have bilateral pulmonary contusions and will require increased FiO_2 and high levels of PEEP to maintain adequate oxygenation, even when both lungs are ventilated. Those with a high Thoracic Trauma Severity score in the setting of blunt trauma and pulmonary contusion are more likely to progress to ARDS potentially necessitating early, aggressive management of mechanical ventilation.[325]

Although chest trauma requiring pneumonectomy has historically resulted in mortality approaching 100%, a recent review of the National Trauma Data Bank found 261 cases of pneumonectomy following trauma (163 penetrating and 98 blunt) with an overall in-hospital mortality of 60%.[326] Intraoperative deaths are the result of uncontrollable hemorrhage, acute right ventricular failure, and air embolism. Patients who survive the initial procedure are at risk for early postoperative morbidity and mortality. Fluid management may be complicated by the need to weigh ongoing resuscitation against the treatment of right ventricular failure. Blunt thoracic trauma requiring pneumonectomy is often associated with abdominal and pelvic trauma. Volume replacement must be judicious, and the use of a pulmonary artery catheter (placed with care in a postpneumonectomy patient) or TEE may be beneficial. Echocardiography will also play an important role in assessing right ventricular function and pulmonary hypertension. Treatment of right ventricular failure after traumatic pneumonectomy is difficult.[327] During hypovolemic shock a disproportionate increase occurs in pulmonary vascular resistance with respect to systemic vascular resistance,[328] as well as frequent mortality with combined hemorrhagic shock and pneumonectomy.[329] With severe right heart dysfunction it is desirable to maintain a higher preload than normal. Several therapeutic approaches have been used to treat right ventricular failure, including close monitoring of pulmonary artery pressure, the use of diuretics for volume overload, and administration of pulmonary vasodilators. Because this injury is rare, and the number of patients reported in the literature is small, the best therapy is difficult to identify. A recent case report describes the use of nitric oxide to successfully treat pulmonary hypertension after posttraumatic pneumonectomy.[330] Extracorporeal support also has been used to sustain patients through the perioperative period, although the technical challenges are substantial and successful weaning may require days to weeks on bypass (see also Chapter 85).[331]

Tracheobronchial injury can result from either blunt force or penetrating trauma. Penetrating injuries are usually more promptly diagnosed and treated. Blunt trauma most commonly results in an injury to the tracheobronchial tree within 2.5 cm of the carina and may initially be unrecognized. The presence of subcutaneous emphysema, pneumomediastinum, pneumopericardium, or pneumoperitoneum, without apparent cause, should alert the practitioner to possible tracheobronchial injury.[332] Despite bronchoscopy and helical CT scanning, a small injury may never be delineated. If the resultant injury is an incomplete tear, it may heal with stenosis, subsequent atelectasis, pneumonia, pulmonary destruction, and sepsis. When surgery is required for a delayed, incomplete tracheobronchial injury, pulmonary resection may be required if significant tissue destruction has occurred, whereas complete transection may be amenable to reconstruction with preservation of pulmonary tissue. The level of injury dictates the surgical approach. Cervical injuries are approached through a transverse neck incision, left bronchial injuries via a left thoracotomy, and tracheal or right main bronchial injuries via a right thoracotomy. In the cervical region it is sometimes possible to access a longitudinal tear of the posterior membranous trachea by opening the anterior trachea and operating around the ETT.

CHEST INJURIES: TRAUMATIC AORTIC INJURY

Traumatic aortic injury (TAI) must be ruled out in any patient with a high-energy injury, such as occurs with a motor vehicle accident or a fall from a height. The incidence of TAI has decreased in recent years because of the increased presence of airbags in motor vehicles; most of the cases in the past decade have been caused by side-impact collisions.[333] Aortic injury occurs most commonly just distal to the left subclavian artery and is the result of sheer forces between the mobile heart and aortic arch and the immobile descending thoracic aorta. TAI is manifested as a continuum of injury from a small intimal flap to free transection contained by the surrounding mediastinum and pleura. The diagnosis is most commonly made by CT scan of the chest with intravenous contrast, which has a sensitivity comparable to aortography.[334] Surgical or endovascular repair is indicated for most patients with TAI because of the high risk for rupture in the hours and days after injury with endovascular repair being the preferred option in the absence of contraindication. Selective nonoperative management of high-risk patients with TAI has been described.[335,336] Treatment is similar to that in patients with uncomplicated type B aortic dissection and consists of β-adrenergic blockade to minimize the cardiac rate–pressure product.

CHEST INJURIES: RIB FRACTURES

Rib fractures are the most common injury resulting from blunt chest trauma. The fracture itself generally requires no specific treatment and will heal spontaneously over a period of several weeks. Therapy is directed at minimizing pulmonary complications secondary to these fractures, such as pain, splinting, atelectasis, hypoxemia, and pneumonia. Of particular concern are rib fractures in older adults (older than 55 years of age). Older patients with rib fractures have twice the mortality and thoracic morbidity of younger patients with similar injuries. Epidural anesthesia should be used liberally in patients with severe pain, older adults, and patients with preexisting compromised pulmonary function. Data support a 6% decrease in morbidity and mortality in older patients when epidural anesthesia is used[337]; however, a meta-analysis failed to identify a reduction in mortality.[338] Nonetheless, recent guidelines for pain management in the patient with blunt thoracic trauma recommend epidural analgesia over nonregional modalities of pain control.[339] Epidural analgesia may minimize or avoid complications of splinting and pain such as hypoxemia, hypoventilation, the need for tracheal intubation, and the possibility of pneumonia. Endotracheal intubation is reserved for patients who are unable to oxygenate or ventilate or who require protection of the airway.

Fracture of multiple neighboring ribs will result in the flail chest syndrome, characterized by paradoxical chest wall motion during spontaneous ventilation. Not all patients with a flail chest require positive-pressure ventilation, and endotracheal intubation should be reserved for those who meet the usual criteria. Patients who are not initially intubated should be observed closely in the ICU for signs of worsening respiratory function. Increasing cases have been reported of the use of noninvasive positive-pressure ventilation (NIPPV) for lung injury secondary to trauma.[340] For these patients who subsequently require intubation for a surgical procedure, the anesthesiologist will need to determine the safety of extubation postoperatively. NIPPV is associated with fewer cases of pneumonia, which may lead to fewer tracheostomies and decreased ICU length of stay.

A successful technique has been early extubation to a mask delivering continuous positive airway pressure or bilevel positive airway pressure.[341] Concomitant pulmonary injury, especially lung contusion, is commonly associated with flail chest. Pulmonary contusion will cause shunting, which will lead to hypoxemia. This syndrome may progress rapidly in the hours and days after injury. An initially clear chest radiograph does not exclude the possibility of a pulmonary contusion, and, again, close observation is warranted if signs of significant chest wall trauma are present. As with all patients after traumatic injury, a high degree of suspicion along with a continuous search for missed injuries is warranted. No specific therapy exists for a pulmonary contusion, and therapy is directed at the associated injuries or resultant hypoxemia. Early and aggressive implementation of a lung-protective strategy may have a role in patients with significant pulmonary contusion to minimize progression to ARDS.

CHEST INJURIES: CARDIAC INJURY

Blunt cardiac injury is a rare and poorly understood phenomenon that must be considered in any patient who has sustained a frontal impact to the chest. Bruising or edema of the myocardium is functionally indistinguishable from myocardial ischemia and may be causally related in that the pathophysiology of cardiac contusion may involve forcible dislodgement of unstable atherosclerotic plaque. If the patient is hemodynamically stable and the ECG does not demonstrate conduction disturbances or tachyarrhythmias, blunt cardiac injury can be safely excluded.[342] If either a new tachyarrhythmia or conduction disturbance subsequently develops or the patient has unexplained hypotension, other causes (hypovolemia, renal failure) should be ruled out first. If the workup is negative, TTE should be performed. Right ventricular dysfunction resulting in hypotension may be overlooked while more common causes of hypotension in the trauma patient are being evaluated. TEE is superior to TTE in obese patients or those with injuries to the chest wall that make it difficult to obtain adequate acoustic windows, but it will generally require intubation and deep sedation to perform. Once diagnosed, blunt cardiac injury should be managed as ischemic cardiac injury, with completion of resuscitation and then careful control of fluid volumes, administration of coronary vasodilators, and monitoring and symptomatic treatment of rhythm disturbances. Anticoagulation with aspirin or heparin should be approached on a case-by-case basis as determined by the patient's other injuries. Cardiology consultation is appropriate if the patient may benefit from coronary angiography followed by angioplasty or stenting of stenotic vessels.

Patients with penetrating cardiac trauma and blunt trauma causing rupture of one or more chambers (usually the atria) are often not seen by the trauma center because of a frequent rate of prehospital mortality.[343] Those who do not die immediately of free exsanguination into the thoracic cavity will have pericardial tamponade and can be extremely unstable in the first minutes after admission. This condition is diagnosed by clinical suspicion, focused assessment with sonography for trauma (FAST), and direct inspection during ED thoracotomy. Relief of the tamponade and clamp or suture control of the cardiac injury may allow restoration of spontaneous circulation and necessitate urgent transition to the OR for definitive hemostasis and chest closure. Cardiopulmonary bypass may be required for support during repair of cardiac injuries.

ABDOMINAL INJURY

The need for exploratory laparotomy, once the mainstay of the trauma surgeon, has declined because FAST and high-resolution CT have reduced the incidence of negative abdominal explorations, whereas angiographic embolization of hemorrhaging vessels in the liver and spleen has reduced the need for open procedures. Urgent celiotomy, when it does occur, will typically follow the principles of damage control, as described earlier.[344] The abdomen is opened and packed tightly in all four quadrants. Systematic exploration is undertaken in each quadrant in turn, with time taken only for control of hemorrhage and rapid staple closure of open gastrointestinal injuries. The abdomen is packed open at the end of the procedure, a sterile drape is used to cover exposed viscera, and the patient is moved to the ICU to complete resuscitation. Definitive treatment of nonlethal injuries and restoration of bowel continuity are deferred until a second operation 24 to 48 hours later.

Anesthetic management of emergency celiotomy should follow the principles of early resuscitation outlined earlier. Adequate intravenous access is required, as well as continuous arterial pressure monitoring. Use of cell salvage devices can reduce the patient's exposure to banked blood, although reinfusion is generally deferred if there has been significant contamination by bowel contents. A rapid infusion system is advantageous for preservation of intravascular volume and normothermia during periods of heavy bleeding. Subsequent abdominal surgeries will be needed in hemodynamically stable patients and should not present unusual anesthetic challenges. Subsequent reconstructive procedures can become technically difficult as scarring and adhesions develop; the anesthesiologist should be prepared for a long anesthetic procedure with the potential for significant hemodynamic compromise.

Selected Patient Populations

TRAUMA AND PREGNANCY

Trauma to pregnant patients is associated with a frequent risk for spontaneous abortion, preterm labor, or premature delivery, depending on the location and magnitude of the mother's injury.[345] Trauma is the leading nonobstetric cause of death in pregnant women with nearly double the mortality rate.[346] Early consultation with an obstetrician is desirable for any pregnant trauma patient, for both immediate management and long-term follow-up. The best treatment of the developing fetus consists of rapid and complete resuscitation of the mother. Trauma patients in the first trimester of gestation may not realize that they are pregnant; for this reason, human chorionic gonadotropin testing is part of the initial laboratory studies for any injured woman of childbearing age. Serious trauma occurring during the period of fetal organogenesis may induce birth defects or miscarriage because of the effects of medications, pelvic irradiation, or hemorrhage leading to placental ischemia. Indicated radiologic tests should not be deferred but shielding of the pelvis should be provided whenever possible.[347] Patients who do not spontaneously miscarry should be advised of the potential risks for birth defects and be referred for counseling if desired.[348] Dilatation plus curettage of the uterus is advisable after miscarriage to avoid toxicity arising from retained products of conception.[349]

Trauma occurring in the second or third trimester of pregnancy necessitates early ultrasonographic examination to determine fetal age, size, and viability. Monitoring of the fetal heart rate is indicated if the pregnancy is sufficiently advanced that the fetus would be viable if delivered. Preterm labor is very common in this population and should be treated with β-adrenergic agonist drugs or magnesium at the direction of the obstetrician. Delivery should be delayed if the fetus is not an unacceptable metabolic stress on the mother. Delivery by cesarean section is indicated if the mother is in extremis, if the uterus itself is hemorrhaging, or if the gravid uterus is impairing surgical control of abdominal or pelvic hemorrhage.[350] Placental abruption can occur in response to substance abuse or abdominal trauma and can precipitate life-threatening uterine hemorrhage. Emergency cesarean section is indicated in these cases. The Kleihauer-Betke blood test can be used to determine if fetal blood has leaked into the maternal circulation[350]; if positive, administration of anti-Rh_0 immune globulin is recommended for any Rh-negative mother carrying a Rh-positive fetus. By the third trimester the uterus is sufficiently enlarged to compress the inferior vena cava when the patient is positioned supine, thereby impairing venous return to the heart and contributing to hypotension. Left lateral uterine displacement is indicated to treat this problem. If the patient is immobilized on a long spine board because of concern for a thoracic or lumbar spinal fracture, the whole board can be tipped to the left. Because the gravid uterus displays abdominal contents upward, elevating the head of the bed may also be required to improve ventilation.

PEDIATRIC TRAUMA PATIENTS

While the overall proportion of pediatric trauma patients compromises a minority of trauma center admissions, traumatic injuries remain the leading cause of death for children aged 1 to 14 years of age.[2] Motor vehicle crashes, drowning, falls, and burns constitute most of the mechanisms for traumatic injury.[351] A disproportionate number of pediatric trauma patients (~80%) have an associated TBI; such injuries are responsible for more than half of all deaths.[351,352] The initial priorities of trauma assessment and management are the same for children and adults; nonetheless, several particularities must be considered, including differences in airway anatomy, the normal range of physiological variables, and other anatomical differences (see also Chapter 77).[33,352]

Successful management of the pediatric airway constitutes the foundation and initial step in pediatric trauma resuscitation because hypoxia and respiratory compromise are the most common causes of cardiac arrest.[352,353] Preceding airway management, a high degree of caution must be exercised to immobilize the cervical spine in patients with dangerous mechanisms that increase the risk of spinal injuries. Some of these mechanisms include: falls from height greater than one meter or five stairs, axial loading to the head, high-speed and/or rollover motor vehicle crashes, ejection from a motor vehicle, or accidents involving motorized recreational vehicles and bicycle collisions.[354] SCIWORA may be present in up to 35% of children with high-risk mechanisms, and this increased risk precludes clearance of the cervical spine in the same manner as adults.[354,355] Children have a high oxygen consumption rate and react to hypoxia with bradycardia, sometimes even with very brief periods of apnea.[356] The anesthesiologist should be prepared to encounter the following anatomical differences in pediatric patients when managing the airway: a large, protuberant occiput; a small oral cavity; a large tongue; presence of large adenoids and tonsils; and a short and anteriorly displaced larynx.[352,356] These anatomical features can predispose to obstruction, bleeding, and a difficult airway. Pediatric patients should always be considered to have a full stomach, and rapid sequence induction and intubation is the gold standard for airway management.[356] In cases where intubation and mask ventilation are impossible, surgical cricothyroidotomy is considered unsafe in children younger than 12 years of age due to the small size of the cricothyroid membrane and proximity to vocal cords.[33] Needle cricothyroidotomy is preferred as a temporizing solution until other preparations are made. Emergent venous access in children can be challenging; if unable to obtain peripheral access, intraosseous access is recommended.[33] Determination of weight is mandatory to dose medications appropriately and guide fluid and blood component resuscitation. If weight is unknown, a length-based resuscitation tape or specialty stretcher with an integrated scale may be used. Throughout the perioperative period, vigilance for hypothermia should be maintained. Owing to a large surface-to-weight ratio, immature thermoregulation mechanisms, and the effects of general anesthetics, pediatric trauma patients are prone to develop hypothermia.[357] Hypothermia can be particularly detrimental for pediatric trauma patients because up to a 10% decrease in clotting factor activity has been observed for every degree Celsius below normothermia.[357,358]

There are several unique aspects of pediatric trauma resuscitation that anesthesiologists should be familiar with. Due to differences in pediatric coagulation profiles (i.e., decreased levels of procoagulatory proteins and fewer coagulation inhibitors), thromboelastography has an unclear role for diagnosing and treating coagulation disorders.[357] There are no validated scoring systems to determine the need for massive transfusion in children, and a DCR strategy (i.e., transfusion-packed RBCs to FFP to platelets in a 1:1:1 ratio) has not been studied adequately in pediatric patients. Hypotensive resuscitation has not been studied in children and may be hazardous because baseline blood pressures in children closely approximate the lower limits of cerebral autoregulation.[357,359,360] The use of adjuncts such as TXA rFVIIa may have utility in limiting bleeding, but large studies in pediatric patients are presently lacking.[359,361]

OLDER TRAUMA PATIENTS

As the world population continues to increase in age, elderly trauma patients continue to become a growing part of the overall trauma population.[362] Overall mortality among elderly trauma patients is higher than among younger adults; injured patients over age 74 years are at considerably higher risk for mortality.[363] Elderly trauma patients frequently present with lower ISS, but more often sustain severe injuries to the head and lower extremities.[364]

When managing elderly patients with trauma, the effects of aging on physiological function and the impact of preexisting conditions and medications must be carefully considered. Equivalent traumatic injuries will have a markedly more serious outcome in the elderly than in younger victims (see also Chapter 65).[363,365] Elderly patients may be taking multiple medications such as anticoagulants and β-blockers, each of which may worsen traumatic shock by causing severe bleeding and blunting of compensatory responses, respectively. Elderly patients may not have teeth or dentures to help maintain airway patency; edentulous patients are often difficult to mask ventilate, and dentures may loosen and obstruct the airway. Many older adults have decreased chest wall and pulmonary compliance, diminished functional residual capacity, and decreased mucus clearance—all of which have been shown to contribute to a mortality that is double that found in younger patients.[366] In elderly patients with blunt thoracic trauma, each additional rib fracture increases mortality and the risk for pneumonia by over 20%. Intubation may be complicated by degenerative spine changes and kyphoscoliosis. The patient may have a pacemaker or automatic implantable cardioverter-defibrillator in place, as well as artificial cardiac valves or stents. Older adults have thinner skin and are more prone to hypothermia and early development of pressure ulcers. Great care must be taken during intraoperative positioning to avoid secondary pressure injuries. Potential causes of an altered mental status may include delirium, dementia, pain medication, sedatives, increased ICP, and decreased CPP, the latter two of which are most deadly.

A tailored evaluation and management of elderly trauma patients is a crucial factor for improving outcomes.[367] A higher hematocrit, achieved by tighter control of administered fluid, is generally recommended to maintain maximized tissue oxygen delivery. Posttraumatic myocardial dysfunction is a significant risk, particularly if the heart rate is elevated secondary to blood loss, pain, or anxiety. Complex operations or large blood loss should encourage the use of TEE, invasive arterial monitoring, and noninvasive monitors of cardiac output and volume status to guide fluid and inotropic therapy.[163] Older patients will have diminished requirements for postoperative analgesia and may respond to sedative medications with inappropriate agitation.

JEHOVAH'S WITNESS PATIENTS

A trauma patient who refuses blood products requires special management. Early identification and control of hemorrhage are obviously important (see also Chapter 49). Deliberate hypotension to limit bleeding may be helpful. Preoperative and intraoperative phlebotomy should be minimized. The use of salvaged red cells (from intraoperative collection or from a chest drainage system) should be discussed with the patient because some Jehovah's Witness patients will allow the use of salvaged blood provided that the entire system remains in continuity with the vasculature.[368] The use of albumin and other substances derived from circulating proteins should be addressed. Early hemodynamic monitoring is indicated to help determine the role of colloid therapy, vasopressors, and inotropes in maintaining tissue oxygen delivery at the highest possible level. Case reports have described the successful use of rFVIIa and hemoglobin-based oxygen carriers in Jehovah's Witness patients to rapidly correct bleeding and support oxygen delivery, but these agents are not approved for these uses and large case series are not available.[369] In the postacute phase, the use of erythropoietin to promote red cell growth may shorten the period of relative anemia although there is limited evidence.[370]

Postoperative Care

EMERGENCE AND TRACHEAL EXTUBATION

Initial surgery in a trauma patient is followed by a period of monitoring and ongoing treatment in which the anesthesiologist is closely involved, either in the postanesthesia care unit (PACU) or in the ICU (see also Chapter 80). The adequacy of posttraumatic resuscitation must be confirmed, as outlined earlier, and diagnostic studies of the secondary survey completed. Rapid termination of general anesthesia is highly desirable, particularly in patients with an altered level of consciousness or other evidence of TBI before surgery. Change in mental status from the preoperative baseline is an indication for repeat cranial CT and a search for possible metabolic or toxic derangements.

Although neurologic function should be assessed postoperatively, early extubation of a trauma patient should not be taken for granted. Many patients will require continued ventilator support because of CNS trauma, direct pulmonary or chest wall trauma, massive transfusion, upper airway edema, or ongoing intoxication. Box 66.12 lists the criteria for extubation after urgent or emergency trauma surgery. If any doubt exists about the patient's ability to meet these criteria, the patient should be transported to the PACU or ICU with the ETT in place. Appropriate analgesic medication should be administered, with sedation if necessary. Twelve to 24 hours of support allows confirmation of successful resuscitation and surgical repair, hemodynamic equilibration, titration of appropriate analgesia, and resolution of intoxication. Many patients can be tracheally extubated easily and safely at this time; those who cannot are at high risk for the development of MOD—heralded by the development of posttraumatic ARDS—and will usually require days to weeks of subsequent intensive care.

ACUTE PAIN MANAGEMENT

Trauma patients present significant pain management challenges to the clinician because of multiple sites of injury, protracted episodes of care, complicating psychological and

BOX 66.12 Criteria for Operating Room or Postanesthesia Care Unit Extubation of the Trachea in a Trauma Patient

Mental Status

Resolution of intoxication
Able to follow commands
Noncombative
Pain adequately controlled

Airway Anatomy and Reflexes

Appropriate cough and gag
Ability to protect airway from aspiration
No excessive airway edema or instability

Respiratory Mechanics

Adequate tidal volume and respiratory rate
Normal motor strength
Required fraction of inspired oxygen (FiO_2) less than 0.50

Systemic Stability

Adequately resuscitated (see earlier)
Small likelihood of urgent return to the operating room
Normothermic, without signs of sepsis

emotional issues, and prior or ongoing substance abuse (see also Chapter 81). As with pain management practice in other diseases, trauma patients are frequently undertreated, thus creating a significant source of dissatisfaction. Because trauma patients run the gamut of physiology from healthy young athletes to debilitated older adults, anesthesiologists providing pain management for trauma patients must be prepared for a wide range of needs.

Individual trauma patients will have widely varying requirements for pain medication, so induction of analgesia must be titrated carefully, ideally in a closely monitored environment such as the PACU. Administration of rapidly acting intravenous agents in small doses at frequent intervals until pain relief is achieved is recommended. This allows the practitioner to determine the patient's basal requirements before starting long-acting medications or patient-controlled analgesia. Hypotension in response to analgesics is most commonly indicative of hypovolemia and should prompt a search for occult hemorrhage while further resuscitation occurs.

The need for analgesic medication and the duration of requirement for analgesics will be minimized if a comprehensive emotional support system is available to the patient. Trauma, because of its unexpected nature, carries with it a strongly negative psychological overlay that can have a profound effect on how anatomically based pain is perceived by the brain[371] and on how the patient reacts. After an injury the patient may have legal, financial, and family-based concerns, without the ability to immediately address them. The availability of counselors—religious, financial, or legal—who can help the patient and family with these issues is of enormous benefit. The anesthesiologist can help by communicating to the patient a clear description of the injuries, the probable time required for recovery, and the plan for managing pain throughout the course. The anesthesiologist should refer the patient to counseling services as needed and should be alert to the potential for posttraumatic stress disorder (PTSD) in any traumatized patient.[372] Referral to an experienced psychiatrist or psychologist is appropriate if PTSD is hindering the patient's recovery.

The need for analgesic medication is also influenced by the schedule of physical therapy prescribed for the patient. In general, the more active a patient can be after traumatic injury, the lower the risk for pulmonary complications, venous thrombosis, and decubitus ulcers. Though painful in the short term, the sooner the patient is mobilized, the lower are the analgesic requirements in the long term. Early mobilization demonstrates to the patient the path to recovery and contributes to an improved emotional state. One of the goals of analgesia, therefore, is provision of adequate medication to facilitate physical therapy without so sedating the patient that participation is impossible.

Neuropathic pain arises when direct injury occurs to a major sensory nerve and is common after spinal cord trauma, traumatic amputations, and major crush injuries. Neuropathic pain is characterized by burning, intermittent electrical shocks, and dysesthesia in the affected dermatomal distribution. Neuropathic pain must be identified because it responds poorly to the analgesics used for somatic pain. This diagnosis should be considered whenever pain control is poor or the patient has a rising requirement for medications unexplained by anatomic injuries. First-line therapy for neuropathic pain has been revolutionized by the widespread use of gabapentin, an antiepileptic drug with very strong specificity for this problem.[373] Gabapentin therapy is typically initiated at a dose of 200 mg three times daily, with daily titration upward to a maximum of 2 to 3 g/day. If neuropathic pain persists, selective regional anesthesia or analgesia may be indicated in an effort to break the cycle of spinal cord receptor recruitment.[374]

Regional analgesia (see also Chapters 45 and 46) provided through an epidural or brachial catheter should be considered for any trauma patient with a potential to benefit from this approach because it will spare the use of systemic opioids and facilitate early mobilization.[375] Epidural analgesia produces high levels of patient satisfaction and improved pulmonary function after major thoracoabdominal and orthopedic surgery in elective populations[376]; this is very likely true for the trauma population as well. Regional techniques are less useful when the patient has multiple sites of injury or when fractures or open wounds make placement difficult. Although epidural placement in anesthetized patients is relatively contraindicated because of the potential for occult SCI, the risk-to-benefit ratio in many trauma patients favors placement during surgery, when general anesthesia facilitates appropriate positioning and patient cooperation.

Summary

Trauma touches all ages and classes of patients, from young and vigorous to older and frail. Because of its high prevalence, practicing anesthesiologists will encounter trauma patients throughout their careers. Increased public recognition of the consequences of injury has sparked interest in trauma research and education, with the result that diagnostic and therapeutic techniques have evolved rapidly in recent years. The anesthesiologist, as a perioperative physician, is in the ideal position to understand and apply these new techniques across the trauma continuum.

Acknowledgment

The editors, publisher, and Dr. Thomas E. Grissom would like to thank Drs. Maureen McCunn and Richard P. Dutton for their contribution to this chapter in the prior edition of this work. It has served as the foundation for the current chapter.

Prehospital Care for Medical Emergencies and Trauma

BENN MORRIE LANCMAN, SIMON ANDREW HENDEL, JEROME C. CROWLEY, and YVONNE Y. LAI

KEY POINTS

- After World War II, the subspecialty of prehospital emergency medicine evolved with leadership from doctors in anesthesiology. In many countries, prehospital emergency medicine is considered the fourth pillar along with anesthesiology, critical care, and pain therapy.
- Emergency medical service (EMS) systems differ among and within countries. When these differences were put together, two primary models evolved. In the United States, paramedics provide prehospital care for all patients (single-tiered system). In many European countries, EMS-physicians lead the prehospital care for patients requiring advanced life support (two-tiered system).
- The core approach of managing prehospital emergencies involves basic life support and advanced life support.
- Rapid, simultaneous assessment and triage form the cornerstone of prehospital care—the use of a primary survey and limited diagnostic adjuncts can ensure transport to the most appropriate care setting.
- In major trauma, prehospital care must limit the time spent on the scene, control hemorrhage, and expedite transport to a trauma center, ideally via a rescue helicopter. Although this approach has been used both in the military (e.g., Vietnam) and in civilian locations, it is not always possible. Prehospital intravenous fluid resuscitation for major trauma varies in approach. Patients with penetrating torso injuries and hemorrhagic shock may benefit from limited intravenous fluid resuscitation and permissive hypotension, in particular in urban settings. Prevention of the lethal triad of hypothermia, acidosis, and coagulopathy is of paramount importance.
- In acute coronary syndrome and stroke, achieving rapid reperfusion of the ischemic tissue is the priority. Because only specialized centers provide 24-hour cardiac catheter service or stroke teams, rapid transport to acute myocardial infarction or stroke centers is critical. In response to a myocardial infarction, morphine, oxygen, nitrates, and aspirin are the main components of prehospital therapy. Fibrinolysis for myocardial infarction has been used with significant success in the prehospital setting but requires very close supervision by EMS physicians.
- The future of EMS will likely see an increased use of telehealth, which can narrow the time gap between the hospital and the field. This will facilitate improved field and hospital diagnostics and treatments, and ensure more efficient handoffs when arriving at the receiving hospital.

Background

The heritage of the modern emergency medical service (EMS) can be traced to the late 1700s with the approach to triage and forward patient retrieval of Napoleon's chief surgeon, Dominique Jean Larrey. Later, in 1832, in London, transport carriages were introduced for cholera patients. The rationale for the introduction of such carriages was that the "curative process commences the instant the patient is put into the carriage."[1] Americans adopted this concept during the American Civil War, when General Jonathan Letterman, a Union military surgeon, created the first organized system in the United States to transport injured patients. Civilian EMS systems in the United States evolved subsequently—with the first one forming in Cincinnati in 1865.

It was nearly a century later in the 1960s when changes in medical technology and knowledge joined forces with political will to formalize the concept of prehospital care. In the early 1960s, two major clinical advances occurred—cardiopulmonary resuscitation (CPR) for life support of the patient in cardiac arrest, and the development of portable external defibrillators. These two advancements provided the foundation of advanced cardiac life support (ACLS). This, in turn, led to the concept of trained community members to respond to emergencies to improve outcome.

In 1965, President Lyndon Johnson created the President's Committee for Traffic Safety, which published the report *Health, Medical Care, and Transportation of the Injured*. It identified motor vehicle crashes as a significant public health concern. The committee recommended a national program to reduce highway deaths and injuries.

Additionally, in 1966, a report was released by the National Academy of Sciences titled *Accidental Death and Disability: The Neglected Disease of Modern Society*. It emphasized the need to address the quality of prehospital emergency medical care as it recognized that ambulances were ill-equipped and inappropriately staffed.

These two documents paved the way for the Highway Safety Act of 1966, which was passed by Congress and ultimately led to the formation of the National Highway Traffic Safety Administration (NHTSA) within the Department of Transportation. The NHTSA developed a national EMS curriculum which, in 1969, became the standard for emergency medical technician (EMT) training in the United States. In 1973, Congress further passed the EMS Systems Act, granting funds for the development of regional EMS systems. As a result, various states established a total of approximately 300 EMS regions with associated federal support. In the United States, the responsibility of EMS then shifted from federal to state level in 1981, which created heterogeneity in the system.

During the same period of time, EMS and prehospital medical systems were similarly evolving in most developed countries outside the United States. All had unique aspects and points of difference, mostly influenced by the local geography, political will, origin, and resources. The fundamental mission of EMS systems remained common—to deliver the best possible prehospital care to the right patients, in the right timeframe, and to transport them safely to a higher level of care.

Some systems evolved to be predominantly staffed by physicians, while others were staffed almost exclusively by paramedics with no to very minor physician involvement, and most fell somewhere between the two—with at least the capacity for a combined physician-paramedic crew.

BASIC VERSUS ADVANCED LIFE SUPPORT AND BEYOND

CPR was developed in 1960 when the American Heart Association started a program to train physicians in mouth-to-mouth resuscitation (expired air resuscitation) with associated external chest compressions. This led to the development of a tiered system: basic life support (BLS) and advanced life support (ALS) to denote the different skillsets of responders in an organized EMS.

First responders (such as police officers, firefighters, EMTs, and paramedics) are generally the first to arrive to an emergency and can provide medical assistance. A tiered system with different skillsets helps to make the scope of practice and role delineation clearer in the often chaotic prehospital environment.

BASIC LIFE SUPPORT

The adult BLS sequence is circulation-airway-breathing (C-A-B). The goal is to ensure continuous blood (and by proxy, oxygen) supply to major organs. Firefighters, lifeguards, and police officers are often BLS certified because they are often the first to a scene and the application of BLS does not require specialized medical knowledge, per se.

CPR and the use of an automated external defibrillator (AED) are considered BLS skills and the increasing availability of automated defibrillators makes it ever more likely that “unskilled” members of the community will be the first to deliver defibrillation in the event of an out-of-hospital cardiac arrest (OHCA). BLS also includes simple airway maneuvers such as chin lift, jaw thrust, and oxygen administration. For trauma care, basic skills include airway management such as simple airway maneuvers, oropharyngeal and nasopharyngeal airways, and bag-mask ventilation.

Besides CPR and automated external defibrillation, BLS also includes hemorrhage control, and fracture and cervical spine immobilization. In the trauma patient who has suffered a primary traumatic cardiac arrest, CPR is unlikely to be of benefit and may, in fact, detract from useful life saving interventions. This relative controversy will be discussed later in the chapter. The decision not to perform CPR in the resuscitation of the arrested trauma patient should be made by personnel specifically trained at least at the ALS level—and probably only in advanced prehospital systems that include suitably skilled physicians or intensive care paramedics.

ADVANCED LIFE SUPPORT, INTENSIVE CARE–LEVEL PREHOSPITAL CARE

The knowledge and skills necessary to successfully perform ALS are built upon the firm foundations of BLS. For example, even the most experienced prehospital or trauma practitioner relies upon basic airway maneuvers to maintain oxygenation when more sophisticated techniques have failed.

In the prehospital environment, ALS is most often provided by paramedics (advanced EMT practitioners). In many jurisdictions, however, there is a level of prehospital care above ALS, and, outside the United States, combined physician-paramedic crewed helicopter emergency medical services (HEMS) are common. In places where doctors are not part of a HEMS response, paramedics with advanced and intensive care skillsets are often used. This enables the resuscitation bay to essentially be taken to the patient, and, in addition, for advanced resuscitation to be maintained throughout transport. The rationale for these advanced prehospital teams is to maximize the opportunity, while minimizing the time delay for delivery of the advanced trauma care that severely ill or injured patients need.

The provision of advanced, hospital-level interventions (e.g., advanced airway management such as endotracheal intubation, thoracostomy, resuscitative thoracotomy, and commencement of blood product transfusion) remain areas of significant controversy when applied to the prehospital environment. The question of whether it is better to prioritize caring for the patient in the field (“stay and play”) or to prioritize expedited transport (“scoop and run”) is an old and polarizing one. In environments where transport times are prolonged due to expansive distances (such as Australia), delivering advanced interventions early can be lifesaving. On the other hand, prolonging scene times and delaying presentation to definitive trauma care in order to initiate treatment in the field is unlikely to be in the patient’s best interest in other settings. In all mature trauma systems (incorporating the prehospital and in-hospital phases of care), a balance will need to be struck between these two competing priorities.

The reality is that on a population-wide scale, it is rare for anyone to need the advanced services of an EMT, let alone an HEMS prehospital resuscitation team. It is difficult, therefore, to adequately power a study to show a difference between the various models of prehospital care, if such a difference exists. As such, individual prehospital and in-hospital trauma systems have adapted to fulfill the perceived requirements of their population and account for areas of operational limitation.

Training for ALS EMTs now requires a rigorous educational background, and includes skills in advanced and invasive monitoring, diagnostics, and management. Systems functioning at or above the ALS level provide a more comprehensive assessment and stabilization of the trauma patient. In the United States, providers certified at the paramedic level (EMT-P) can perform any of these interventions, whereas providers certified at the intermediate level (EMT-I) may perform a select subset of these skills. Other jurisdictions have comparable delineations of skillset.

Emergency Medical Technician and Paramedic-Based Emergency Medical Service Systems

Specially trained EMTs and paramedics form the bulk of the workforce of EMS systems in North America and in many other developed nations. Under U.S. law, physicians, functioning as EMS directors, are required to approve the medical operations of the EMS systems they oversee. This includes communication, clinical operations, and governance.

In the United States, there are three levels of EMTs based on their level of education and training: EMT-basic (EMT-B), EMT-intermediate (EMT-I), and EMT-paramedic (EMT-P). The primary focus of the EMT-B is to provide basic emergency medical care (using BLS skills) and transportation to a healthcare system. They typically staff nonemergency ambulances and may also respond to nonemergency calls. EMT-I practitioners, or advanced EMTs, provide basic and limited advanced emergency medical care and transportation. They are regulated differently and their skills range between BLS and ALS depending on state regulations. EMT-P is the highest skillset within EMTs in the United States. They undergo intensive 1- to 2-year training in advanced prehospital emergency care. They are ALS trained and can perform procedures such as endotracheal intubation, administration of drugs, and manual defibrillation.

In many other countries, paramedics are required to complete bachelor-level university degrees and are nationally or regionally registered by regulatory bodies—in a similar way that medical practitioners are licensed. In some regions, such as in most states of Australia and in many countries in Western Europe, intensive care paramedics have advanced skills in complex medical and trauma management as well as casualty access and rescue skills.

Primary Survey and Initial Assessment at the Scene

The primary survey is usually performed in the same ABCDE (airway-breathing-circulation, disability-exposure) mnemonic format that is widely known from ACLS. Since 2010, the American Heart Association has recommended changing their ABC approach (airway-breathing-compressions) to CAB (compressions-airway-breathing), emphasizing circulation prior to airway. This is particularly relevant for someone in cardiac arrest to bring focus to chest compressions. It is also relevant to the trauma patient suffering critical bleeding. If you can hear the bleeding, you should stop it first!

The approach, therefore, in the prehospital major trauma patient is C-ABCDE. Strategies for prehospital management of critical hemorrhage are discussed in more detail elsewhere in the chapter, but broadly, options include direct pressure, deep wound packing, use of novel hemostatics (there are several on the market), and tourniquets for extremity hemorrhage (the Combat Application Tourniquet [CAT] is the most widely used). Specific techniques can be used for major maxillofacial hemorrhage, which include nasal packing, or balloon tamponade devices (such as the Rapid Rhino), dental splints, and immobilization of the jaw with a hard, cervical spinal collar.

Novel approaches using resuscitative endovascular balloon occlusion of the aorta (REBOA) to manage critical bleeding in pelvic trauma in the absence of chest trauma are not yet widespread. Indeed, prehospital REBOA has been used successfully on only one documented occasion by London’s Air Ambulance. It remains an area of significant controversy and of limited evidence.

Once critical bleeding has been identified and temporarily controlled, moving through the remainder of the primary survey in a rapid yet methodical way is warranted. If there is airway (A) obstruction, the obstruction should be cleared and the airway secured if necessary. While it will often be appropriate to perform a rapid sequence intubation in the prehospital environment, it may not always be necessary or beneficial. A balance must be struck between delaying transfer, likely disposition once in hospital, distance to definitive care, and skillset available. Most prehospital services continue to secure the cervical spine with a hard collar for transport and this would be applied at this time.

Breathing (B) becomes the next priority; after the airway is cleared and possibly secured, a patient’s breathing is assessed by observing respiratory rate, pattern, and degree of chest rise and fall. Supplemental oxygen and assisted ventilation may be indicated. Immediately reversible causes of potentially fatal chest trauma, such as tension pneumothoraces, may also be identified and treated with minimal delay to patient transfer. In the case of tension pneumothoraces, many advanced prehospital services (especially those with medical-paramedic HEMS crews) have adopted a finger thoracostomy approach to chest decompression, rather than needle thoracostomy, to achieve a more definitive endpoint early and minimize the risk of reaccumulation of the pneumothorax in transit. Of course, this definitive care may not be available prehospital in all jurisdictions.

Circulation (C) is next assessed by palpating pulses, checking for heart rate, pulse quality and regularity, measuring blood pressure, and again assessing for sources of hemorrhage. As an approximation, a palpable carotid pulse corresponds to a systolic blood pressure of at least 70 mm Hg, and a palpable radial pulse to a systolic blood pressure of 80 to 90 mm Hg.

Also, as part of the primary survey, large-bore intravenous access is obtained. Early fluid management in the trauma patient has been a contentious issue in trauma management for many years. There has been much discussion in the scientific and prehospital literature in relation to the role of crystalloid fluid in the early resuscitation of the trauma patient. Over the past decade there has been a significant shift away from the aggressive use of crystalloid and a shift toward early administration of blood products in the prehospital environment. Some prehospital retrieval services carry red cells only, whereas some (particularly in the United Kingdom) also carry freeze-dried plasma products. In the trauma patient with no concomitant head injury, achieving a systolic blood pressure of 90 mm Hg is ideal (so-called "permissive hypotension"). The only caveat to this blood pressure target is in the head-injured patient. If head injury is present or suspected, then hypotension should be avoided. Indeed, available evidence suggests that in the presence of severe head injury, a single episode of systolic hypotension below 90 mm Hg may double mortality.

As part of the assessment of circulation, suspected long bone fractures can be immobilized with CT-6 (or equivalent) splints and the patient may be packaged in a vacuum mat for transport. If the prehospital team has the capability and expertise, an extended focused assessment with sonography in trauma (e-FAST) exam can be performed as part of the circulatory assessment. This may assist in identifying pneumothoraces before transport and may also reveal other major sources of bleeding that can be relayed to the receiving center.

Disability (D) is measured using the Glasgow Coma Scale (GCS). The GCS is made up of three parts: eyes, verbal response, and motor response. The best patient response is recorded. In the GCS, a maximum of 4 points are allocated for eye opening, 1 being unresponsive and 4 being eyes open; a maximum of 5 points are allocated to verbal response, with 1 being unresponsive and 5 being alert and oriented; and a maximum of 6 points are allocated to motor response, with 1 being unresponsive and 6 for the patient who obeys commands. The highest possible score is 15 and the lowest score possible is 3. As a general rule, patients with GCS score of 8 to 9 have alteration in their conscious state significant enough so as to no longer have the ability to protect their own airway. Assessment of exposure and environment (E) and measures to defend core body temperature completes the primary survey and patient packaging process.

It is important to note that the management of the trauma patient in the prehospital environment relies on concurrent activity within the team. The key to prehospital diagnosis and treatment is the initiation of important treatment as problems are identified, while minimizing unnecessary time spent at the scene. The focus of professional prehospital teams is avoiding the "therapeutic vacuum," or time where nothing useful is happening for the patient.

On arrival, and having assessed the scene, the prehospital care team must rapidly obtain a relevant and focused history of the patient and the events surrounding the incident. In the case of trauma, the ATMIST and AMPLE mnemonics provide a useful framework for gathering key initial information. ATMIST stands for age, time of incident, mechanism of injury, injuries sustained, vital signs (initial and subsequent), and treatment given so far. The AMPLE approach can then be applied to gather specific and relevant history. AMPLE stands for allergies, medications (regular and acute), past history, last meal (menses, tetanus injection) and the events surrounding the injury.

MONITORS

Standard monitors in the prehospital setting include pulse oximetry, noninvasive arterial blood pressure monitoring, electrocardiography (ECG), temperature, and capnography. Indeed, the standards of patient monitoring in the mature EMS or prehospital retrieval service are as high as in most critical care areas of a major hospital. The main difference, of course, is that the monitor display itself must be capable of withstanding the environmental rigors of the prehospital environment, be easily carried, and have a long battery life. There are many commercially available monitors (and ventilators, infusion pumps, and other equipment for that matter) that are approved for flight and designed to be robust across a range of transport platforms and environmental extremes.

POINT OF CARE ULTRASOUND

Portable and affordable ultrasound machines now make point-of-care (POC) ultrasound in the prehospital setting common. In Europe, the United Kingdom, and Australia, where physicians are active in the prehospital management of patients, this becomes even more practical to use. A Dutch observational study showed that 61% of ultrasound examinations impacted decisions in 88% of patients both in prehospital and once they reached definitive care.[2] POC ultrasound is not limited to cardiac arrest; as mentioned earlier, abdominal ultrasound has also been shown to impact treatment decisions and in experienced hands, does not significantly delay treatment.[3]

Out-of-Hospital Cardiac Arrest

Survival from sudden cardiac arrest is highly dependent on early CPR and early defibrillation. Communities have placed an increasing emphasis on bystander CPR, community accessible AEDs, and rapid response of EMS providers.[4]

When the EMS arrives on the scene, the "Universal Treatment Algorithm" is started.[5] Chest compressions continue until cardiac monitoring is placed and it is determined whether defibrillation is appropriate. Pharmacotherapy and airway management remain poorly defined. Optimal airway management in OHCA has not been established, and studies have shown that resuscitation with medications increases likelihood of the return of spontaneous circulation (ROSC) without improved outcome.[6]

The likelihood of ROSC will depend in large part on the etiology of the cardiac arrest as well as the presence of adequate bystander CPR. By far the most common cause of OHCA is from cardiac pathology.

ACUTE CORONARY SYNDROME

Over 5.5 million patients in the United States present to emergency departments with chest pain as their primary complaint. Almost 50% of these patients arrive by ambulance.[7] Any mature EMS system needs to be well equipped to manage this common and potentially life-threatening presentation. For a patient presenting with chest pain in the prehospital setting, three things need to happen: (1) diagnosis be made, (2) treatment commenced, and (3) triage to facility.

PREHOSPITAL DIAGNOSIS AND ELECTROCARDIOGRAPHY

The prehospital ECG is essential in the assessment and triage of patients with chest pain and making the diagnosis of ST-segment elevation myocardial infarction (STEMI). It has been shown through multiple studies that prehospital ECGs are not only technically feasible but they also decreased the time from presentation to reperfusion.[8] This finding has been replicated in rural settings.[9] A recent study looking at clinical outcomes with use of prehospital ECGs showed that the adjusted risk of mortality was lower in cases where ECGs were used.[10]

PREHOSPITAL TREATMENT AND FIBRINOLYSIS

Primary percutaneous coronary intervention (PCI) is the treatment of choice for STEMI patients if this therapy can be performed within 90 minutes of onset or less. When a patient is unable to receive mechanical reperfusion within that time window (either because of geographic isolation or arrival at a non-PCI community hospital) then evidence supports the use of fibrinolysis followed by PCI within 24 hours.[11] It was subsequently demonstrated that a paramedic-based prehospital fibrinolysis program was practical and feasible in reducing time to treatment with favorable clinical outcomes.[12]

MECHANICAL CIRCULATORY SUPPORT

Prehospital Extracorporeal Cardiac Life Support

Recently extracorporeal cardiac life support (ECLS) has been introduced to the prehospital environment for treatment of OHCA patients in some very select settings. The use of mechanical ECLS in the prehospital setting remains controversial. Whether initiated in the field or in the emergency department, there is insufficient evidence to guide broad-based adoption of this practice. Multiple case reports have demonstrated some utility, but this therapy should not detract from high-quality ACLS.[13-15]

Respiratory Distress

Respiratory distress is a common complaint necessitating prehospital medical intervention.[16] Management requires rapid identification of emergent conditions and subsequent intervention to prevent further deterioration. Unfortunately, dyspnea, the perception of respiratory distress, can be influenced by a variety of factors and patient complaint alone is insufficient to identify the underlying cause or its severity. Early stabilization of respiratory function regardless of the underlying pathology is important to avoid significant morbidity and mortality. Even for anesthesiologists who are not participating in prehospital care, it is important to have a familiarity with these conditions as emergent or urgent surgical patients may present with dyspnea that is not fully evaluated and their initial management will fall on the anesthesia team in the perioperative period.

EVALUATION

Initial evaluation of the patient in respiratory distress is structured to identify patients at risk for rapid progression to respiratory failure and identify the need for invasive support. Respiratory rate is an easily obtainable vital sign, and a rate of more than 30 breaths per minute would be defined as abnormal. It is important to consider that other factors, such as anxiety and intoxications, can affect the respiratory rate. Other physical signs include stridor, upper airway obstruction, inability to speak in full sentences, and cyanosis. Pulse oximetry has emerged as a standard monitor for detecting hypoxemia, although it should be noted that a patient can have significant respiratory pathology while maintaining a clinically acceptable oxygen saturation.[16] Developing a differential of dyspnea can be challenging but may be simplified if the clinician considers the underlying organ system likely to be the culprit. Table 67.1 provides a comprehensive, but not exhaustive, list of causes of dyspnea that an anesthesiologist should be familiar with in the emergent and prehospital setting.

MANAGEMENT

Initial management of the patient with dyspnea in the field involves stabilization when possible and rapid transport to a facility that can provide definitive care. Interventions in the prehospital setting can range in complexity depending on the needs of the patient and the skillset of the providers. Common interventions include supplemental oxygen for the management of hypoxia, inhaled bronchodilators for wheeze, and bag-mask ventilation or intubation for fulminant respiratory failure. Prehospital care also will often include needle decompression for suspected tension pneumothorax (although increasingly finger thoracostomy is performed) and epinephrine administration for suspected anaphylaxis. Comprehensive management of these conditions is beyond the scope of this chapter; however some pearls related to respiratory distress are in Box 67.1.

Neurologic Injury and Head Injury

Diseases of the central nervous system pose a significant challenge to the prehospital provider. Many of the familiar techniques used by clinicians to gather important information are unavailable. An unconscious or post-ictal or post-seizure patient will not be able to provide useful clinical history and even gathering basic identifying information can be a challenge. These issues are magnified in the prehospital environment. This section will provide an overview of the major priorities and challenges that face the prehospital provider when confronted with a neurologic event in the field. For further clinical detail on the management of these conditions please refer to the Chapters 84 and 66.

TABLE 67.1 Etiologies of Dyspnea

Organ System	Conditions
Pulmonary	Airway obstruction Pulmonary embolus Noncardiogenic pulmonary edema Acute respiratory distress syndrome Pneumonia Anaphylaxis Obstructive sleep apnea Asthma Cor pulmonale/pulmonary hypertension Aspiration Pleural effusion Malignancy Chronic obstructive pulmonary disease
Cardiac	Cardiogenic pulmonary edema Acute coronary syndrome Tamponade Pericarditis Congenital cardiac disease Valvular heart disease Cardiomyopathy
Neurologic	Cerebrovascular accident Intracranial hemorrhage Organophosphate poisoning Multiple sclerosis Guillain-Barré syndrome Tick paralysis Amyotrophic lateral sclerosis Polymyositis Porphyria
Trauma	Pneumothorax (tension vs. simple) Hemothorax Diaphragm injury Tamponade Rib fractures
Abdominal	Acidosis/shock from abdominal catastrophe Splinting from abdominal pain Pregnancy Ascites
Psychogenic	Panic attack Somatization disorders Hyperventilation syndrome
Metabolic/endocrine	Toxic ingestion Diabetic ketoacidosis Renal failure/metabolic acidosis Electrolyte abnormalities Fever Thyrotoxicosis
Infectious	Pneumonia Epiglottitis
Hematologic	Carbon monoxide poisoning Cyanide poisoning Anemia Sickle cell crisis (acute chest syndrome)

TRAUMATIC BRAIN INJURY

Traumatic brain injury is a major cause of morbidity to patients who have been traumatically injured. From the moment of injury all care should be focused on maximizing the survival of remaining neuronal tissue. Specific parameters outlined in Chapter 66 are followed with particular emphasis on minimizing secondary injury.

BOX 67.1 **Pearls (Precepts, Dicta) for Respiratory Distress**

- Rule out life-threatening, rapidly progressive causes such as tension pneumothorax or acute coronary syndrome prior to initiating a more thorough workup for causes of shortness of breath
- A normal oxygen saturation does not mean a patient is without significant respiratory pathology
- The majority of patients with respiratory distress are related to pulmonary or cardiac causes; however, the astute clinician should always keep in mind additional causes in the appropriate clinical context
- Chronic conditions tend to be better tolerated than acute ones. For example, chronic mitral regurgitation is well tolerated until it becomes severe whereas acute mitral regurgitation is a medical emergency
- The acuity of onset of the condition is helpful for determining the cause. For example, a patient with a chronic neuromuscular disorder who presents with an acute worsening likely has an additional explanation for his or her shortness of breath
- There is no clinical finding that rules out pulmonary embolism and a low threshold for further workup should be maintained in the appropriate patient
- Unnecessary supplemental oxygen does not have a benefit and likely leads to preventable harms

SPINAL CORD INJURY

Patients with spinal cord injury (SCI) present unique challenges to the prehospital provider. Patients rarely injure themselves in locations where access and maintenance of spinal precautions is easy. Balancing the risk of worsening or causing injury must be weighed against the necessity of moving the patient to a suitable transport platform. It is important to note that transporting a patient as carefully as practical is very unlikely to generate enough force to cause an injury that is not already present.

With this in mind, the safest approach for handling potential SCI cases is to assume such an injury is present in any mechanism that could result in significant SCI, but also not to delay lifesaving treatment in preference of spinal precautions.

Spinal immobilization techniques have received increased scrutiny over the past decade. The hard-cervical collar is no longer considered the "magic bullet" of cervical spine immobilization. Hard spinal boards are also falling out of favor with many emergency services around the world. Regardless of the jurisdiction, if "hard" immobilization devices are used, there is a shift toward using them for as short a period of time as possible. Depending on the expected transport time from the scene there may be a role for early application of Philadelphia- or Aspen-style collars with transport in a vacuum mat. The main advantage of cervical spine collars is that they alert the receiving hospital that this patient might have c-spine injury and needs according attention. It is possible that this can be achieved with a soft collar, avoiding some of the risks of prolonged hard collar immobilization. This is particularly relevant for the older patient with fragile skin or for the patient requiring prolonged transfer.

ACUTE STROKE MANAGEMENT

Stroke is a much feared and potentially debilitating condition. While it can be more difficult to identify the location of a particular stroke without a detailed neurologic exam, the ability to provide targeted reperfusion therapy for large vessel stroke has seen a drastic change in the expected outcome for those patients. Much like percutaneous interventions for heart attacks, interventional neuroradiology is able to drastically change the clinical trajectory of a ”brain attack.” Minimizing the ischemic time for neuronal tissue becomes the priority. Thus, early diagnosis, activation of neuroradiology, and timely transport become essential to achieving optimal clinical outcomes. This has resulted in some jurisdictions deploying thrombolysis in the field. Recent major studies were halted early due to evidence of benefit for those patients who received thrombectomy. As such, transporting these patients to a center that can provide clot retrieval is important. To maximize the speed of diagnosis, mobile stroke units have been developed that contain a portable computed tomography scanner and capacity for “teleradiology” to make a radiologic diagnosis in the field. While these platforms have been launched with significant enthusiasm, they remain the exception across the developed world, and potentially of questionable cost-benefit.

SEIZURE

Seizure is a common presenting complaint and makes up approximately 1% of all emergency department admissions. First responders are therefore often required to provide emergency medical management and, where appropriate, supportive care during transport to hospital. The detailed management of status epilepticus is covered in Chapter 57, but patients with status epilepticus have improved outcomes when treatment is commenced in the field by EMS providers.

ALTERED MENTAL STATUS

Altered mental status covers a broad range of conditions affecting a patient’s cognition. In the prehospital environment, first responders may be required to assess, treat, and safely transport people with a range of underlying disorders. Patients may be drug affected, head injured, delirious, or suffering from a wide range of medical or neurosurgical disorders. Prehospital providers may need to treat patients with altered mental status in their own home, at a motor vehicle accident scene, or in any number of complex environments. As with any scene, providing a safe environment for the providers as well as for the patient is of utmost importance.

When the need arises, pharmacologic sedation may be utilized to facilitate safe transport to a healthcare facility. Providers are expected to assess and treat any easily reversible causes of altered mental status such as hypoglycemia or hypoxia, but many precipitants are outside the scope of a field diagnosis. Collateral history is increasingly important to determine the timeline for the changes in mental status and how far the patient’s current altered state has departed from normal.

Prehospital Trauma

Trauma remains a significant burden of disease globally and is the greatest cause of death for those under 40 years of age. As has been demonstrated in previous chapters in this text, early access to definitive care is the single greatest modifier in the survivability of a major traumatic event. Trauma patients’ need for advanced and specialized trauma care begins at the moment of injury, hence delays in transport or delivery of definitive care contribute to poor outcome. Accordingly, the prehospital management of trauma patients has the potential to start the process of recovery from the point of injury. It is essential that anesthesiologists working in receiving hospitals understand the capacity, unique challenges, and limitations of providing care in the prehospital environment so they can be prepared to continue with ongoing care. Understanding what can (and cannot) be done in the prehospital environment minimizes duplication and stagnation of care in-hospital, and is essential to avoiding the therapeutic vacuum.

TRIAGE

Triage is the process of prioritizing and allocating resources based on clinical need and urgency. Routinely, higher-level responses are dispatched to the most acutely sick or injured patients. First responder systems and processes differ within and among nations. Depending on the specific first responder system of the country, the first response providers could be any combination of road ambulance (staffed by paramedics/EMTs of variable skillsets or physicians), higher acuity “fast-cars” containing a physician or advanced practice EMTs (sometimes referred to as intensive care paramedics), or HEMS crews. The triage system in most developed EMS systems is activated via a standard phone number. This number varies from region to region and can be reached via landline or cellular networks (911 in the United States, 999 in the United Kingdom, 000 in Australia, and 112 from cellular telephones worldwide). Once activated, trained nonmedical dispatchers utilize a standardized script to determine urgency and location, and provide bystander advice and support. An appropriate emergency medical resource is tasked to respond. Alternatively, the system may be activated for a partner emergency service such as police or fire to respond to an incident, or all three emergency services may be required at an incident site.

SCENE SECURITY

For providers who predominantly practice in-hospital, it can be easy to take the relative luxuries of lighting, environmental control, and personal security for granted. For first responders and others who deliver trauma care in the prehospital environment, there are many hazards that need to be considered and addressed to ensure as safe an environment as possible—for themselves and their patient.

Some examples of hazards that need to be considered and/or addressed are included in Table 67.2.

The priority on arrival at the scene is to ensure safety for self, the crew, bystanders, and then the patient. It is also important to rapidly assess the number and nature of injured, so a further triage can occur. If the number or severity of injured exceeds the capacity of the on-scene crew, then additional resources should be requested. For the purposes of this chapter we will consider only one injured patient. For considerations in the mass casualty context, refer to Chapter 68.

TABLE 67.2 Environmental and Human Hazards

Environmental Hazards	Human Hazards
▪ Live power cables ▪ Fire ▪ Spilled chemicals/fuel ▪ Other vehicles/cars/traffic ▪ Enclosed spaces/inadequate ventilation ▪ Unsafe/stable buildings/trees ▪ Extreme weather (sun/rain/snow) ▪ Biological hazards	▪ Active shooters ▪ Distressed family/friends ▪ Intoxicated bystanders ▪ Panicked/distressed crowds ▪ Complex or insecure scenes (e.g., subsequent to terrorist attack, conflict zones)

PRIMARY AND SECONDARY SURVEYS

First responders have been trained to approach the primary survey with the same mindset and using the same principles of Advanced Trauma Life Support (ATLS). The focus of the prehospital primary survey is to perform a rapid initial assessment identifying, assessing, and treating life-threatening injuries. It differs from the in-hospital primary survey in that there is the inherent imperative to secure and package the patient for transport at the same time as assessing and treating. In some circles providers have looked to dichotomize the clinical approach in the field between the two extreme positions of "stay and play" and "scoop and run." In reality, neither approach presents a one-size-fits-all, and providers need to consider the individualized requirements of their patient based on injury, skillset, transfer time, resources, and environmental constraints—and then adapt the clinical approach to balance these priorities and optimize the patient's care.

STAY AND PLAY

The stay and play concept refers to the approach of maximizing the amount of definitive clinical treatment that occurs in the field before transport to the receiving hospital. By providing maximal appropriate treatment in the field, the intent is to minimize the clinical insult of the injury or illness. The rationale for stay and play is that if the patient needs advanced trauma care from the moment of injury, then that care should be delivered to them early on. In reality, it is not as simple as merely transporting a one-person trauma resuscitation bay to the patient. Treatments provided in the field can be more difficult to achieve. Despite ever-increasing standards of prehospital resuscitation and more easily available diagnostic equipment, reduced sterility and limited diagnostics and monitoring remain an issue for prehospital teams. As such, each treatment needs to be considered in relation to its potential benefits weighed against the possible harm in delayed primary transfer. In recognition of this tension, many high-performing teams have developed focused, standard operating procedures to maximize their chance of first attempt success and minimize the time taken to perform tasks. A commonly performed intervention is rapid sequence intubation. "Kit-dumps" (Fig. 67.1) are commonly used both as a cognitive aid and as a workspace tool to improve team performance in the field. The strongest clinical prehospital team is one that possesses complementary and overlapping skills. It remains an inescapable reality that teams that are jointly staffed in physician/advanced paramedic configuration tend to have a broader scope and extended range of practice.

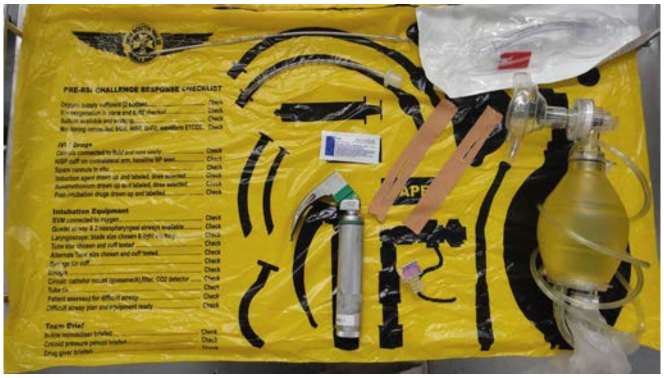

Fig. 67.1 "Kit-dumps" are commonly used both as a cognitive aid and as a workspace tool to improve team performance in the field. (Courtesy MedSTAR, Adelaide, South Australia.)

SCOOP AND RUN

The focus with the scoop and run approach is to minimize scene time and transport the patient to definitive care as soon as possible. Proponents of scoop and run argue that the time to definitive care is what makes the difference, hence the patient should be moved as quickly as possible to a trauma center—with only the barest of essential life-saving interventions performed at the scene. Depending on the expected transport time, this philosophy may be entirely appropriate for many trauma patients. Any interventions performed in this context would be for immediate lifesaving interventions only.

FURTHER CONSIDERATIONS

Prehospital providers are also expected to gather as much useful information from the scene as possible to guide ongoing care. Current medications, collateral medical history, and photos of the accident scene are all tasks that are expected to be undertaken whenever possible.

Transport destinations are often predetermined. Effort is made in most systems to deliver patients to the appropriate clinical location wherever possible. For example, a suspected myocardial infarction should be transported to a center where PCI is possible. Other acute subspecialty centers include stroke, extracorporeal membrane oxygenation, trauma, pediatrics, and burns. Factors such as patient preference and, in certain jurisdictions, level of insurance can also be considered where the clinical setting allows.

BALANCED RESUSCITATION

The early control of major hemorrhage has become the focus of any significant trauma resuscitation. As we gain greater understanding of the consequences of acute traumatic coagulopathy as well as the downstream impact of our clinical resuscitation, there has been a transition away from crystalloid-based fluid resuscitation toward "hemostatic" resuscitation fluids. Many ambulance services around the world now carry fractionated blood products—usually packed red blood cells, but an increasing number are carrying plasma. There is active research underway on the early administration of tranexamic acid (TXA) and the impact this may have on clinical outcomes after injury. The CRASH-2 trial demonstrated a mortality benefit when TXA was administered within 3 hours of injury. The hypothesis is that early application may result in greater benefits, although the trial was justifiably criticized for nonhomogeneity of trial sites. Challenges that still need to be addressed include issues such as blood crossmatching, fluid warming, stock control, and cost. There may also be a role for administration of clotting factor concentrates, but this has yet to translate into evidence.

HEMORRHAGE CONTROL

Together with the increased use of blood products in the field there has been a growing array of interventions available for stopping bleeding. The American College of Surgeons (ACS) has been coordinating a nationwide "Stop the Bleeding" campaign in the United States to improve the use and knowledge of hemorrhage control by bystanders. Techniques such as direct pressure, wound packing, and tourniquet application have been introduced to the bystander population.

ANTIFIBRINOLYTICS

The debate around the efficacy and safety of TXA use in the acute severe trauma patient continues. The results of the CRASH-2 trial have been adopted in many trauma systems. On the other hand, many remain unconvinced given the significant heterogeneity of trial sites in the study. The CRASH-2 trial did show a reduction in death from bleeding in trauma patients who received a 1-g intravenous dose of TXA within 3 hours of injury. This benefit did not extend if the first dose was given beyond 3 hours, where the trend was toward complications from thrombosis. There is also some concern that fibrinolysis is not occurring in all bleeding trauma patients and conceptually antifibrinolytic therapy may not be indicated. Additional trials such as the PATCH study are investigating whether targeted use of TXA conveys any survival benefit.

TOURNIQUETS

A CAT correctly placed can significantly reduce the volume of blood loss and arrest hemorrhage in time to transport a patient to definitive care.

RESUSCITATIVE ENDOVASCULAR BALLOON OCCLUSION OF THE AORTA

London's Air Ambulance (known more commonly as London HEMS) has pioneered the use of REBOA in the field for the management of patients with severe bleeding that previously would have been unlikely to survive to hospital. They have field-deployed REBOA multiple times with an overall positive result. The majority of the cases where REBOA had been used involved significant pelvic trauma. The evidence base for REBOA use is expanding. Yet, on the other hand, in a mature trauma system, patients eligible for REBOA may in fact receive definitive care in the operating room instead. The main question now is whether this type of highly specialized intervention is beneficial to implement in other contexts—or whether it truly has a mortality benefit. Perhaps there may come a time when REBOA, or something similar, will become the standard for hemorrhage control in the field.

FUTURE DIRECTIONS AND CHALLENGES

The burden of trauma is growing. With an aging population, more densely populated urban centers, heavier road use, and accelerating technological possibilities for care, the challenges (and opportunities) for first responders are immense. Below are some of the challenges and active areas for investigation currently being explored. As anesthesiologists we need to remain informed and open to the evolution of clinical fields that we partner with and work within.

TRAUMA TRIAGE

The time from incident or injury to the notification of emergency services can either be immediate or significantly delayed. Efforts have been made to automate part of the process. Many modern cars have crash detection and emergency notification built in. Companies such as OnStar provide timely notification to emergency services in the event of a vehicle crash. As more cars are fitted with detailed analytics, there is potential for emergency services to be notified directly when a vehicle is involved in an incident of sufficient force to result in injury.

Point-of-Care Diagnostics

As POC devices become smaller, more reliable, and more affordable there is potential for front-line medical providers to perform rapid assessments to further triage and prioritize patients and their medical needs. Ultrasound is the first device that is likely to be widely adopted at the front line—and already has been deployed in many prehospital services around the world. It is relatively cheap, portable, robust, and has a growing body of evidence to support its use.

The impact of POC diagnostics could be further enhanced with greater use of telemetry and telemedicine. The transmission of live feeds from emergency services to the receiving hospital could provide hospital staff with the information necessary to expedite appropriate care—for example surgical services. Combining field and telemedicine in this way has garnered significant interest from organizations that provide care in the most remote and austere of environments, such as mining companies and the military. The potential application of advanced telemedicine and real-time clinical support for a severely injured or unwell patient aboard a ship at sea is immediately obvious. The two-way nature of telemedicine would also enable hospital staff to support operators in the field, potentially reducing the need for every front-line provider to be an expert in interpretation. Although telemedicine will never replace technical skills, it may greatly enhance clinical decisions.

Overdose/Toxicology/ Environmental Exposure

In contrast to the relatively controlled confines of a modern hospital, prehospital providers are truly confronted with the unknown. In addition to the clinical presentation of the patient there are significant issues that need to be considered when ensuring no further harm occurs to either patients, bystanders, or first responders.

Environmental toxins, chemical exposures, armed patients, or nearby assailants are an unfortunate reality we need to confront. First and foremost, it is the responsibility for any prehospital provider to ensure they are safe. This may require that access to patients be delayed to allow time for police, fire, and/or utility providers to secure the scene. Many EMS units (particularly in the United States) have responded to this challenge with the development of specialized "tactical units." These providers are given additional training to allow them to operate in potentially hostile environments.

The remaining discussion will assume that scene safety has been achieved and that front-line providers have access to the patients.

EVALUATION

An anesthesiologist should have an appreciation of common environmental exposures and toxidromes that may be present, particularly because often these patients can have a concomitant surgical condition that will require management. Evaluation of the intoxicated patient is often challenging and limited to the clinical exam and history obtained from nearby persons. Empty pill containers and other environmental clues can be helpful, but may not be present.[17] If an environmental exposure is suspected, care should be taken to avoid exposure to the emergency response personnel and the patient's clothing should be placed in a secure enclave to prevent further exposure.[17] In the event of significant biologic/chemical/radiation exposure, expert consultation should be obtained to ensure safety of first responders and treating clinicians. While many laboratory tests exist to detect ingested substances, it is important that prehospital providers be familiar with common clinical toxidromes as these may be the only clue to the etiology of the overdose.

MANAGEMENT

As with most emergency management, initial treatment is directed toward stabilizing vital signs before progressing to specific management of any environmental or toxic exposures. Decontamination is also indicated in environmental exposures; this includes removing the patient from the exposure, removal of the patient's clothing, and surface decontamination when indicated.[17] Once these are stabilized further interventions can be attempted. In addition to vital signs, other rapid tests in the field include a 12-lead ECG and a blood glucose. Finally, with the current epidemic of opioid abuse, empiric administration of naloxone should be considered in the appropriate patients. If transportation to a hospital is likely to be delayed, then consultation with toxicology experts should be considered. Table 67.3 is a substantial list of different agents by presenting clinical finding. Table 67.4 lists common ECG findings of selected agents.

ENVIRONMENTAL EXPOSURES

Anesthesiologists should further be familiar with environmental exposures. These include hypothermic and hyperthermic injury. Frostbite refers to the phenomenon of tissue freezing leading to severe microvascular injury and eventual cell death. This can lead to significant morbidity including limb loss and substantial pain. Prehospital management is limited as one of the most devastating treatment failures of frostbitten extremities is freezing-rewarming-refreezing. Therefore, rewarming should not be attempted in the field if there is any chance of it being interrupted. Wet clothing should be removed and the affected area immobilized and protected from physical trauma if possible. If significant cold injury is present and re-warming is attempted, care must be taken as the sudden return of cold blood to the heart can precipitate ventricular dysrhythmias and subsequent cardiac arrest.[18]

Burn injuries are very common but fortunately the majority are only minor injuries. Detailed anesthetic considerations for management of the patient with burns are addressed elsewhere in this book (give chapter here). Specific prehospital management for severe burns focuses on stopping any ongoing burn injury, securing an airway where necessary, and providing adequate analgesia. Many jurisdictions will have a specialist burns center that EMS providers can transfer patients to for definitive care, weighed against the need for transport to the nearest hospital. Considerations for transport to a tertiary burn center are outlined in Fig. 67.2.

Horizons in Prehospital Care

The trend in prehospital care over the last several decades has been toward bringing high-quality care to the roadside. By reducing the therapeutic vacuum, patients receive lifesaving interventions at an earlier time in their disease process hopefully translating to reduced morbidity and mortality. The increasing use of real-time data, predictive analytics, and telemedicine will enable front-line providers to assist in earlier diagnostics and more tailored therapies, and enable hospital-based services to implement plans based on needs identified in the field. The capacity to save lives is going to continue to increase as prehospital and hospital-based providers work in concert for the benefit of their patients.

TABLE 67.3 Clinical Findings and Associated Agents

Clinical Finding	Agent
Miosis	Cholinergics, clonidine, carbamates, opioids (EXCEPT meperidine), organophosphates (pesticides), phenothiazines, pilocarpine
Mydriasis	Anticholinergics, sympathomimetics (albuterol), withdrawal from narcotics
Coma (important to rule out hypotension first)	Alcohols (ethanol, ethylene glycol), tricyclic antidepressants, thallium, toluene, heavy metals (lead), lithium, hypoglycemics (check blood glucose), arsenic, SSRI/SNRIs, antihistamines, opioids, benzodiazepines, barbiturates, carbon monoxide, cyanide, clonidine, insulin (check blood glucose), isoniazid, other sedative-hypnotics
Seizure (history of seizure disorder will increase likelihood)	Hypoglycemics/insulin (check blood glucose), organophosphates, sympathomimetics, salicylates, tricyclic antidepressants, bupropion, cocaine, camphor, chlorinated hydrocarbons, propranolol, phencyclidine, heavy metals (lead), lidocaine, lithium, withdrawal from anti-epileptics, methylxanthines (theophylline, caffeine), methanol, nicotine, amphetamines, ethanol withdrawal
Diaphoresis	Sympathomimetics (cocaine, amphetamines), organophosphates, salicylates, phencyclidine/ketamine
Dry skin	Antihistamines, anticholinergics
Blisters	Barbiturates, mustard gas, snake and spider envenomation
Flushed skin	Niacin, anticholinergics, carbon monoxide
Cyanosis (check oxygen saturation)	Nitrates, nitrites, ergotamine, aniline dyes, dapsone, phenazopyridine
Bradycardia	β blockade, opioids, anticholinesterases, anti-arrythmias (amiodarone, digoxin), calcium channel blockers, clonidine, cholinergics, alcohols
Tachycardia	Cocaine, amphetamines, anticholinergics, antihistamines, alcohol withdrawal, phencyclidine, ketamine, theophylline, caffeine, thyroid hormones, tricyclic antidepressants
Hypothermia	Opioids, carbon monoxide, insulin, hypoglycemics, sedatives, alcohols
Hyperthermia	Neuroleptic malignant syndrome (decreased reflexes, rigidity), serotonin syndrome (hyperreflexia, clonus), salicylates, sympathomimetics (cocaine, amphetamines), alcohol withdrawal, anticholinergics, antipsychotics, antidepressants, nicotine
Hypotension	Calcium channel blockers, clonidine, arsenic, cyanide, aminophylline, anti-hypertensives, antidepressants, sedatives, opioids
Hypertension	Thyroid supplements, cocaine, amphetamines, anticholinergics, nicotine, caffeine, sympathomimetics
Tachypnea	Salicylates, nerve agents, metabolic acidosis secondary to ingestion, pneumonitis from inhalation
Bradypnea	Sedatives, alcohols, opioids, marijuana

TABLE 67.4 EKG Findings in Overdoses

Segment/Interval	Appearance	Agent
P wave	Absent	Digoxin, cholinergics
PR interval	Prolonged	Calcium channel blockers, β-blockers, magnesium
QRS interval	Prolonged	Type 1 anti-arrhythmics (lidocaine), antihistamines, cocaine, tricyclic antidepressants
ST segment	Scooped	Digoxin
QT interval	Prolonged	Many agents, methadone, antipsychotics most relevant.
T wave	Peaked	Acidosis leading to hyperkalemia
T wave	Flattened	Lithium
U wave	Present	Lithium, caffeine, theophylline, albuterol,

Burn Center Referral Criteria

A burn center may treat adults, children, or both.

Burn injuries that should be referred to a burn center include:

1. Partial thickness burns greater than 10% total body surface area (TBSA).
2. Burns that involve the face, hands, feet, genitalia, perineum, or major joints.
3. Third degree burns in any age group.
4. Electrical burns, including lightning injury.
5. Chemical burns.
6. Inhalation injury.
7. Burn injury in patients with preexisting medical disorders that could complicate management, prolong recovery, or affect mortality.
8. Any patient with burns and concomitant trauma (such as fractures) in which the burn injury poses the greatest risk of morbidity or mortality. In such cases, if the trauma poses the greater immediate risk, the patient may be initially stabilized in a trauma center before being transferred to a burn unit. Physician judgment will be necessary in such situations and should be in concert with the regional medical control plan and triage protocols.
9. Burned children in hospitals without qualified personnel or equipment for the care of children.
10. Burn injury in patients who will require special social, emotional, or rehabilitative intervention.

Excerpted from Guidelines for the Operation of Burn Centers (pp. 79-86), Resources for Optimal Care of the Injured Patient 2006, Committee on Trauma, American College of Surgeons

Severity Determination

First Degree *(Partial Thickness)*
Superficial, red, sometimes painful.
Second Degree *(Partial Thickness)*
Skin may be red, blistered, swollen. Very painful.
Third Degree *(Full Thickness)*
Whitish, charred or translucent, no pin prick sensation in burned area.

Percentage Total Body Surface Area (TBSA)

Fig. 67.2 Indications for transfer to a tertiary burn center. (Courtesy American Burn Association. https://ameriburn.org/public-resources/burn-center-referral-criteria/.)

Acknowledgment

The editors and publisher would like to thank Drs. Peter Nagele and Michael Hupfl for contributing a chapter on this topic in the prior edition of this work. It has served as the foundation for the current chapter.

Biological, Natural, and Human-Induced Disasters: The Role of the Anesthesiologist

DANIEL W. JOHNSON, WILLIAM P. MULVOY, and STEVEN J. LISCO

KEY POINTS

- Natural disasters such as earthquakes, hurricanes, floods, tsunamis, and tornadoes have the ability to cause massive interruptions in the normal provision of health care.
- Anesthesiologists possess a combination of knowledge and procedural skills that make them extremely valuable in the immediate and ongoing response to large-scale disasters; to do so, they and their colleagues must be willing to modify their traditional workflow in order to best meet the needs of victims while also serving the needs of other patients.
- Anesthesiologists who travel from resource-rich to resource-limited environments to provide rescue medical care must cope with a number of unanticipated challenges, including lack of familiarity with infectious diseases which have been eradicated from first-world nations, and the management of these diseases.
- Anesthesiologists who travel to disaster-ravaged areas are exposed to a variety of physical and mental stressors that can have an impact on them for months or years after an event.
- Because of the very high early mortality following some natural disasters such as tsunamis, local healthcare systems can be overwhelmed and many local healthcare workers are either lost or displaced. As a result, anesthesiologists who are able to travel to victim countries and provide temporary aid can provide much needed support for the community.
- Although hurricanes tend to have fewer immediate fatalities than earthquakes or tsunamis, their severity and the subsequent flooding can cripple the healthcare system and the physical plants, including clinical and educational facilities.
- When disasters induce shortages of medications, fluids, and supplies, as resulted from Hurricane Maria in 2017, global conservation of existing supplies and avoidance of waste are essential.
- Following a massive terrorism-induced disaster such as the September 11, 2001 attack on New York City, health systems were encouraged to develop more formal triage plans, with particular emphasis on clinical access centers in areas surrounding potential disaster sites.
- In addition to natural disasters, mass shootings are also challenging the healthcare systems. In the United States, 1123 people have been killed by mass shootings since 1966. Accordingly, all anesthesiologists and other providers must be prepared to provide care in the aftermath of these heinous events.
- As acts of terrorism have become more aggressive in recent decades, anesthesiologists may be more likely to provide care following a chemical, biological, radiological, or nuclear (CBRN) event. To do so, they must have an understanding of the implications of each of these disasters on the community and the providers, and be prepared to modify their practices to best meet the needs of patients and the community.
- One of the highest priorities for healthcare workers after a CBRN event is to take precautions against becoming the next victim. Personal protective equipment (PPE) is of the greatest importance in these situations.
- During an outbreak of a highly dangerous infectious disease, anesthesiologists must understand the mechanisms of transmitting the disease and its management; they are often able to serve as consultants in the design of optimal care pathways to minimize risk to patients and healthcare workers.

Introduction

Large-scale disasters force the human population to address complicated issues often never confronted before, in an attempt to address death and injuries and restore order. For decades, many countries have had in place national, regional, and hospital disaster management plans that focus on preparedness, immediate response, and recovery efforts. The objective of these plans is to minimize further injury or damage by optimizing the use of resources and personnel to respond to mass casualties resulting from both natural and human-induced disasters. Healthcare providers have a special role to play in all such events. Anesthesiologists, because of their unique combination of skills and knowledge, are an extremely valuable part of the overall effort to optimize the health and recovery of disaster victims. In-depth knowledge of pharmacology and physiology, expertise in resuscitation, experience in critical care medicine, and the ability to extinguish pain represent some of the critical knowledge and skills anesthesiologists are able to provide in response to these disasters.

In order to provide the support needed during and after these events, anesthesiologists must be prepared to modify their traditional role in patient care and apply their unique abilities to care for patients in a wide variety of scenarios. If, after a massive natural disaster, a given hospital system has adequate personnel to provide intraoperative anesthesia care, but inadequate physicians to triage and provide resuscitation in the Emergency Department (ED) or in the field, anesthesiologists should volunteer to provide care in these settings. Similarly, for those victims requiring surgical interventions, during the postoperative phase of care, most hospitals will not have sufficient critical care physicians to care for all of the critically injured patients. Anesthesiologists are uniquely suited to temporarily assume the role of intensivist, as they so often do in the operating room. Drawing from their training experiences as well as their backgrounds in intraoperative management of complex surgical patients, all anesthesiologists, whether formally trained in critical care medicine or not, should expect to play a key role in the management of patients in the intensive care unit (ICU) and other settings following a disaster.

To address some of the opportunities and challenges associated with management during and after disasters, this chapter is organized into four distinct sections. Whereas consistent themes exist among all of these realms, each section reveals unique roles for the anesthesiologist in addressing patient and community needs after each type of disaster. The four sections of the chapter are:

1. Natural Disasters
2. Acts of Terrorism
3. Chemical, Biological, Radiological, and Nuclear Warfare
4. Epidemic and Pandemic Infectious Outbreaks

Section 1: Natural Disasters

Natural disasters such as earthquakes, hurricanes, floods, tsunamis, and tornadoes can cause massive disruptions in communities, while also interfering with the normal provision of health care. Prehospital care can be completely disrupted due to damage to roads, and hospital care can be brought to a halt due to lack of water, oxygen, fuel, electricity, and other necessary utilities. Hospitals themselves can be damaged or destroyed by these types of events. Communication can be difficult or impossible following natural disasters due to a combination of damage to telecommunication systems and simultaneous usage overload as families and victims try to locate one another. In this section of the chapter, several historical examples of natural disasters will be examined in order to highlight the critical role of the anesthesiologist in the recovery from these devastating events.

EARTHQUAKES

Earthquakes are capable of inducing an incredible amount of damage in a very brief period of time. Resource-limited areas of the world, suffering from poor underlying infrastructure at baseline, are particularly vulnerable to severe damage following an earthquake. The magnitude 7.0 earthquake that struck Haiti on January 12, 2010 was one of the most devastating natural disasters in modern history, and was an example of how badly a nation's healthcare system can be damaged by this type of event. The death toll in Haiti is difficult to calculate accurately, but nearly all analyses place the number of lives lost at more than 130,000, with 1.5 million people immediately displaced following the earthquake.[1,2] More than 80% of Haitian schools and more than 50% of Haitian hospitals were destroyed.

Healthcare professionals from around the world recognized that a resource-limited nation such as Haiti would require an incredible amount of assistance to recover from the earthquake. Surgeons, anesthesiologists, and healthcare providers from the United States and other nations traveled to Haiti in order to provide initial trauma care, and subsequently to assist in backfilling the jobs of Haitian healthcare workers who were lost in the earthquake. Médecins Sans Frontières, or Doctors without Borders, stated in 2013 that its response to the Haitian earthquake was the largest relief operation in the history of the organization.

Hundreds of healthcare workers from around the world wanted to participate in the recovery effort from the earthquake, however a major limiting factor was the inability to access the sole airport in Haiti. The United States Air Force assumed leadership of the airport and provided air traffic control until Haitian authorities could recover adequately to resume control.[3] Additional immediate support came with the deployment of one of the two United States Navy Hospital ships, the USNS *Comfort*. The USNS *Comfort* and her sister ship, USNS *Mercy*, are enormous oil tankers that have been converted to hospital ships designed to deliver health care to U.S. military personnel during wartime. In reality, they are now more commonly deployed to provide humanitarian aid to disaster-ravaged areas of the world. In 2010, the USNS *Comfort* deployed to the coast of Haiti within 72 hours of the earthquake and subsequently embarked upon the largest disaster-relief operation in the history of these floating hospitals. More than 850 patients received care on the ship during the weeks following the earthquake, including 237 children and one premature newborn.[4] The most common condition treated on the ship was musculoskeletal extremity injury, composing about 40% of the overall reasons for admission.[5] The average length of stay was 8 days and surgery was performed 843 times on 454 patients over the course of 5 weeks. Fifty-eight of the operations were amputations.[6] Anesthesiologists from various U.S. hospitals provided care on the USNS *Comfort*, some as new volunteers and some with prior experience in military and disaster relief (Figs. 68.1 and 68.2).

U.S. NAVAL HOSPITAL SHIP
COMFORT

Fig. 68.3 University of Miami anesthesiologist working in a makeshift operating room on the island of Haiti following the 2010 earthquake. (Photo courtesy Dr. Ralf E. Gebhard, University of Miami Department of Anesthesiology, Miami, FL.)

Provision of medical and surgical care aboard the floating hospital was relatively “normal” when compared with the task of providing care on the island of Haiti itself. Nearly all medical facilities in Port Au Prince were either damaged or destroyed by the earthquake, forcing volunteer healthcare teams to work in makeshift clinics, hospitals, and tent facilities throughout the city. One of the largest such facilities was based out of the United Nations compound at the airport.[7] In the initial days after the earthquake, surgical care was very limited because of a lack of supplemental oxygen, unsterile conditions, and a lack of resources to provide anesthesia. Amputations were performed under local anesthesia until a team of anesthesiologists skilled in single-shot block techniques arrived.[7] Following their arrival, these anesthesiologists were able to facilitate the performance of 1000 operations, including major orthopedic surgery. They were also instrumental in the postoperative care and analgesia of the surgical patients (Fig. 68.3).

Anesthesiologists who travel from resource-rich to resource-limited environments to provide rescue medical care must contend with a lack of familiarity with infectious diseases that have been eradicated from first-world nations. During the Haitian earthquake recovery, this situation confronted anesthesiologists who encountered patients suffering from tetanus. Although not completely eradicated from the United States, few anesthesiologists have any experience caring for patients with tetanus. Caused by the anaerobic bacterium *Clostridium tetani*, tetanus causes severe neck rigidity, trismus, and chest wall immobility. All of these problems create difficulties for anesthesiologists in terms of airway management and maintenance of ventilation. The Haitian population is at an elevated risk to develop tetanus following contamination of wounds because of relatively lower rates of tetanus vaccination compared with other nations. Anesthesiologists who provided care for surgical patients on the USNS *Comfort* reported two cases of tetanus that had impact on their anesthetic care.[8] In one case, the patient was noted to have a small mouth opening as a result of trismus. Following induction of general anesthesia with inhaled sevoflurane, the patient’s total body rigidity was markedly improved. Unfortunately, after receiving multiple anesthetics with muscle relaxation, despite receiving appropriate care, the patient had persistent significant muscle weakness, retention of pulmonary secretions, and ultimately pneumonia resulting in his death. In another case, the patient received repeated general anesthetics, consisting of inhaled sevoflurane without neuromuscular blocking drugs. In this case, the patient fully recovered. The anesthesiologists involved in the care of these tetanus victims noted that though the mouth opening is limited, the nasal airway is unaffected by tetanus, so mask ventilation is possible despite the trismus. They also emphasized the importance of conserving medications such as neuromuscular blocking drugs when one is practicing medicine in a severely resource-limited environment so that the drugs are available for the patients most in need. By applying their expertise in pathophysiology and pharmacology, these anesthesiologists were able to safely and effectively deliver surgical anesthesia to high-risk patients without the use of neuromuscular blocking agents by taking advantage of the neuromuscular blocking properties of potent inhaled anesthetic agents.

The Haitian earthquake response highlighted another critical issue associated with all major disasters: the psychological impact on healthcare workers caring for victims. After returning to the United States following humanitarian missions to Haiti, several anesthesiologists wrote thoughtful essays on the care that they had provided.[9] Anesthesiologists who travel to disaster-ravaged areas are exposed to a variety of physical and mental stressors that can have an impact on them for months or years after the event. Prolonged work hours, inadequate rest, exposure to gruesome traumatic injuries, and witnessing the prolonged pain and suffering of children are some examples of what disaster responders endure. Despite these challenges, healthcare providers are expected to provide optimal medical care, while simultaneously providing psychological support to devastated family members. During the busy hours and days of the immediate response to a disaster, healthcare providers stay focused on the call of duty, which allows them to keep personal emotions at bay. As the critical needs resolve, anesthesiologists and other healthcare providers are forced to deal with the physical, mental, and emotional trauma that they themselves have sustained. One might wonder why healthcare providers would leave the safety of their home nation to purposely expose themselves to this kind of potential anguish. Consistent qualities appear to be present among responders to massive natural disasters: they understand that all human beings have dignity, they sympathize with people who are suffering, and they desire to be part of the healing process.

TORNADOES

While tornadoes tend to be shorter in duration than other natural disasters, they are able to create horrendous damage within seconds to minutes. One of the most destructive storms in American history was the tornado rated EF-5 on the Enhanced Fujita scale that ravaged Joplin, Missouri on May 22, 2011. During the ensuing power outage, some hospitals' backup generators failed, requiring anesthesia care and surgery to be performed by flashlight alone.[10] When hospitals are directly destroyed by natural disasters, as occurred at St. John's Mercy Medical Center in Joplin, one of the biggest challenges for the community is the need to restore the healthcare infrastructure, including access to the electronic health record. With proper disaster preparedness, including contingencies for complete losses of hospitals and clinics, normal patterns of care can be restored within a reasonable timeframe.[11]

Opportunistic infections are another common downstream effect from all natural disasters, including tornadoes. Following the 2011 tornado in Joplin, a cluster of patients suffering from necrotizing cutaneous mucormycosis was observed and required extensive treatment.[12] Anesthesia providers are critically important during "outbreaks" such as this since emergency surgeries to control rapidly expanding infectious diseases are critical to patient survival (Figs. 68.4 and 68.5).

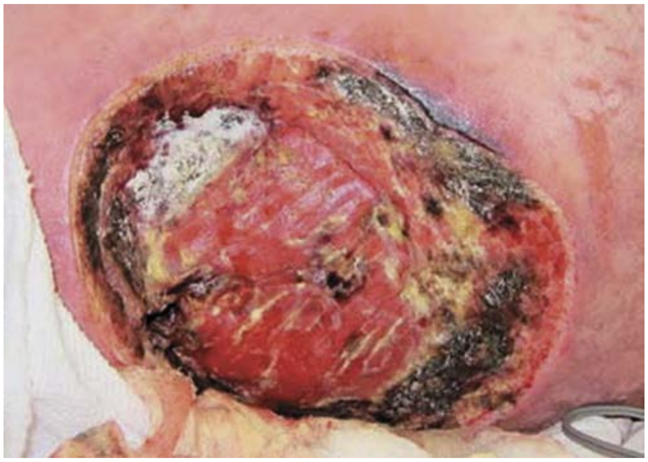

Fig. 68.4 Necrotizing cutaneous mucormycosis of the flank following the Joplin, MO tornado. (From Neblett Fanfair R, Benedict K, Bos J, et al. Necrotizing cutaneous mucormycosis after a tornado in Joplin, Missouri, in 2011. *N Engl J Med.* 2012;367[23]:2214–2215. Published by the Massachusetts Medical Society.)

TSUNAMI

A tsunami is a very large sea wave that results from a submarine earthquake, volcanic eruption, or other significant geologic movement. On December 26, 2004, a massive earthquake, magnitude 9.1 on the Richter Scale, occurred beneath the Indian Ocean and caused one of the deadliest natural disasters in recorded history. The tsunami that resulted from the earthquake created enormous waves that made their way to the shores of 14 countries, including: Indonesia, Sri Lanka, Malaysia, Bangladesh, India, Thailand, and Myanmar. Tsunamis produce a very high ratio of mortality to injury. These waves result from the influx of water on the shores of victim countries causing the immediate death of many people secondary to drowning or the direct impact of waves or debris. The aftermath of a tsunami tends to have three phases. During phase 1, a high number of people are instantly killed. During phase 2, in the hours and days following the initial impact, relief healthcare workers are able to provide life- and limb-saving care to victims of blunt trauma and water exposure.[13] During phase 3, recovery is impeded by a lack of healthcare personnel and a lack of infrastructure needed to provide longer term posttrauma care.

The 2004 tsunami killed more than 230,000 people, injured tens of thousands, and was estimated to have immediately displaced more than 5 million people. One factor in its extreme lethality was the fact that December is the peak tourist season for many of the beaches of Southeast Asia. As is the case with many tsunamis, there was essentially zero warning that deadly waves were about to make landfall. The Aceh province of the Indonesian island of Sumatra was by far the hardest hit area, with waves reaching greater than 25 m in height and with over 100,000 people killed. People on the beach at the time of the tsunami were killed directly, while people farther inland were killed as a result of drowning or impact with massive floating debris (Fig. 68.6).

While there is essentially no role for relief healthcare workers during phase 1 after a tsunami, healthcare workers from nearby regions can and should respond to care for patients during phase 2. Following the 2004

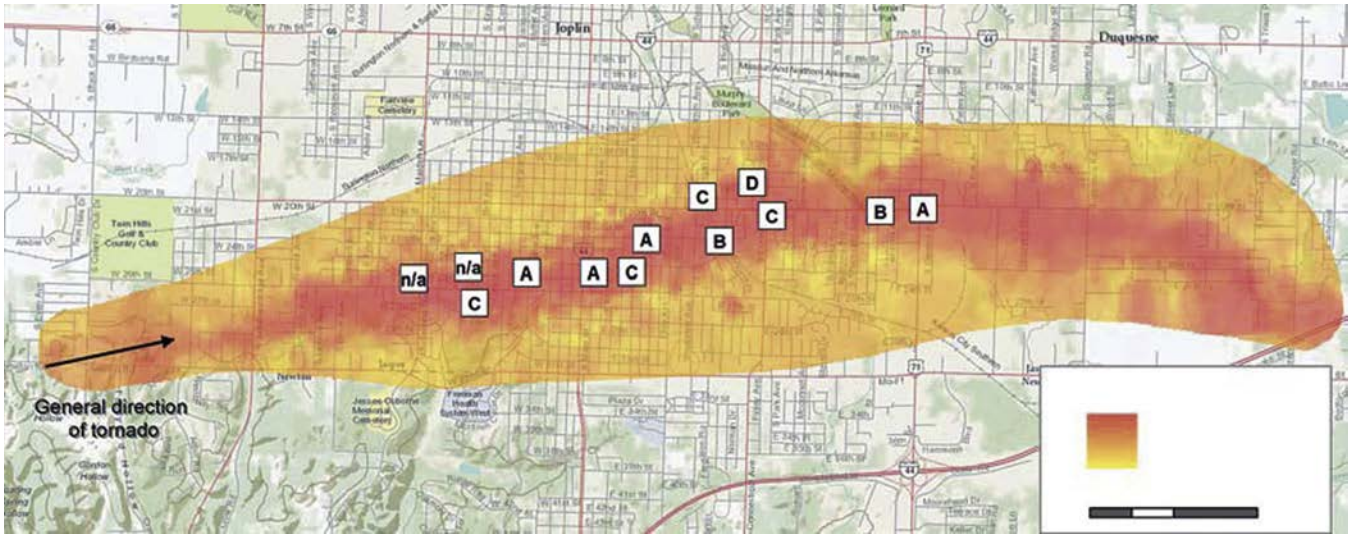

Fig. 68.5 Case locations of mucormycosis with relation to the Joplin tornado course. (Data are from the US Army Corps of Engineers and Esri. From Neblett Fanfair R, Benedict K, Bos J, et al. Necrotizing cutaneous mucormycosis after a tornado in Joplin, Missouri, in 2011. *N Engl J Med.* 2012;367[23]:2214–2215. Published by the Massachusetts Medical Society.)

Fig. 68.6 Debris in the streets of the Aceh province after the December 2004 tsunami. (Photo courtesy Dr. Michael G. Fitzsimons, Massachusetts General Hospital, Boston, MA.)

tsunami, a team of 17 surgeons, 6 anesthesiologists, and other healthcare workers traveled as part of the Thai Red Cross Society for humanitarian mission from Bangkok, Thailand to Phang-Nga, Thailand to provide care. The multidisciplinary team was led by one surgeon and one anesthesiologist. They arrived just 1 day after the tsunami. Over the course of 3 days, the team provided surgical care for 107 patients. The injury profile consisted predominantly of soft-tissue wounds and bone fractures. Halothane was the only inhalational anesthetic available, highlighting the need for anesthesiologists to be nimble in their ability to use older medications during disaster relief.

Most surgical procedures performed in Phang-Nga included general anesthesia following rapid sequence induction. Spinal anesthesia, regional anesthesia, and local anesthesia were also utilized for selected cases. The providers noted an increased incidence of intraoperative oxygen desaturation as compared with findings during other relief operations. The cause for the desaturation is thought to be related to aspiration of seawater and lung contusion secondary to direct impact of waves or debris. In addition to the challenges associated with performing procedures near sites of destruction, providing care can be challenging even if it is being provided remotely relative to the tsunami itself. One common problem is the lack of access to laboratory services. As in post-earthquake anesthetic care, the anesthesiologist may be required to rely on clinical judgment without additional laboratory data to guide decision making in the administration of fluids, electrolytes, antibiotics, and blood products after a tsunami or other natural disaster (Fig. 68.7).

In addition to the regional response, a massive international relief effort was launched in response to the tsunami. In January 2005, Operation Unified Assistance was started as part of the United States response to the catastrophe. Organized by Project HOPE and the U.S. Public Health Service, the USNS *Mercy* was sent from San Diego, California to the Aceh province in Sumatra, representing the first joint effort of military and civilian relief aboard a U.S. Navy ship.[14] U.S. responders to Indonesia were required to demonstrate up-to-date vaccination records for all typical immunizations, receive vaccines for typhoid and hepatitis A, and take prophylactic medication to protect from malaria. Additionally, negative airflow pods were present on the ship to allow for safe care of patients with active tuberculosis. Prior to arrival, all staff members were briefed on the differences in culture they would encounter, and the possible implications for providing care. More than 90% of Indonesian citizens are Muslim, and Islamic Law plays an important role in the day-to-day decision making, including consent for treatment, end-of-life procedures, and other issues for many of the families impacted by the tsunami.

Another serious outcome after a tsunami is often the loss of life of healthcare workers. An estimated 60% of all healthcare workers in the Aceh province died or were

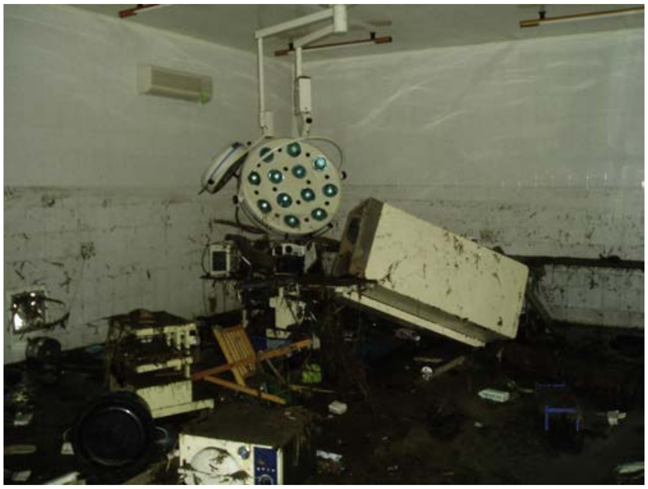

Fig. 68.7 Aceh, Indonesia operating room destroyed by December 2004 tsunami. (Photo courtesy Dr. Michael G. Fitzsimons, Massachusetts General Hospital, Boston, MA.)

missing following the tsunami. Thus, Operation Unified Assistance was prepared to backfill the roles of lost healthcare workers in addition to providing care directly related to the effects of the tsunami. While the USNS *Mercy* was designed for enormous overall capacity, for this operation its clinical footprint consisted of staffing for 3 operating rooms and 50 inpatient beds.

Operation Unified Assistance provided surgical care for 154 patients, but only 8.4% of these were in need of surgery as a direct result of the tsunami.[14] Because of the high mortality to injury ratio in a tsunami, the critical need in Aceh was to compensate for the loss of healthcare workers rather than require large numbers of providers to support patients needing surgical procedures. This differentiates the tsunami experience from the Haitian earthquake experience, with its higher relative incidence of survivable injuries.

For those patients requiring surgery, general anesthesia with inhaled agents supplemented by opioids and neuromuscular blocking drugs was the anesthetic technique of choice. Although access to equipment appropriate for regional anesthesia was limited, one of the primary reasons for this approach was related to the significant language barrier between patients and anesthesiologists. In addition, the clinicians felt postanesthesia recovery from general anesthesia would be easier and safer than for neuraxial or regional, considering all of the circumstances. Another commonly needed and often limited resource includes blood and blood products. In this situation, a total of 122 units of packed red blood cells, 13 units of plasma, and 4 units of cryoprecipitate were transfused during the relief operation.[14] While response to a tsunami has some similarities to the response to a large earthquake, the presence of a modern floating hospital allows the anesthesiologist to employ general anesthetic techniques much more readily than in a tent-based operating suite during inland recovery from an earthquake. At the conclusion of Operation Unified Assistance, a portable monitor and anesthetic medications were donated by the team to the local healthcare facility.

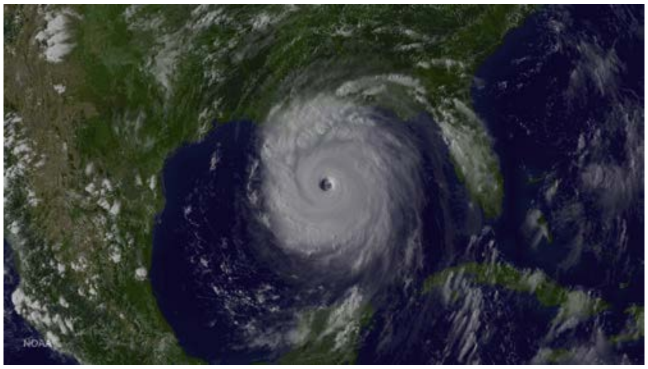

Fig. 68.8 Satellite photo of Hurricane Katrina over the Gulf of Mexico. (Used with permission from the National Oceanic and Atmospheric Administration, National Environmental Satellite, Data, and Information Service. Available from www.nesdis.noaa.gov. Accessed October 26, 2018.)

HURRICANES

A hurricane is a tropical storm with maximum sustained winds of 74 mph (119 km/h) or higher. Hurricanes have the potential to disrupt the normal function of the healthcare system in a variety of ways. When hurricanes reach landfall, the high wind speeds and excessive rainfall make any outdoor movement unsafe, thus paralyzing emergency medical systems and preventing patients from seeking necessary care. With major hurricanes, extensive flooding is a common complication because of the large volumes of rainfall combined with seawater entrained onto land as part of the storm surge. These storms have fewer immediate fatalities than earthquakes or tsunamis, however the ability of hurricanes to cripple the provision of medical and surgical care has numerous downstream consequences. In this section, Hurricane Katrina will be examined as an example of the destructive forces of hurricanes in general.

In August 2005, Katrina started as a storm over the Bahamas, then gained strength over Florida before reaching the Gulf of Mexico. Over the Gulf of Mexico, Katrina reached Category 5 status with top wind speeds of 175 mph. At the time of landfall, the storm was a category 3 hurricane. It produced 8 to 14 inches of rain over southern Louisiana, Mississippi, and Alabama. At some sites on the Mississippi coast, the storm surge was 25 to 28 feet higher than normal tide level and destroyed the majority of structures in its path. In New Orleans, Louisiana, the storm surge sent water over the levees protecting the city, causing flooding in 80% of the city and the need for widespread evacuation. Hurricane Katrina remains the costliest storm in the history of United States at greater than $100 billion in losses, and it was the deadliest hurricane since 1928 (Fig. 68.8; Table 68.1).[15]

The flooding and subsequent displacement of thousands of New Orleans inhabitants following Hurricane Katrina highlight one of the key elements of major natural disasters. In addition to the impact of the hurricane on the healthcare delivery infrastructure, a storm of this magnitude is capable of completely disrupting medical education at the undergraduate and postgraduate levels. New Orleans is home to two major medical schools with

TABLE 68.1 Saffir-Simpson Hurricane Wind Scale

Category	Sustained Wind Speeds	Damage Potential
1	74-95 mph 119-153 km/h	**Very dangerous winds will produce some damage:** Well-constructed frame homes could have damage to roof, shingles, vinyl siding, and gutters. Large branches of trees will snap, and shallowly rooted trees may be toppled. Extensive damage to power lines and poles likely will result in power outages that could last a few to several days.
2	96-110 mph 154-177 km/h	**Extremely dangerous winds will cause extensive damage:** Well-constructed frame homes could sustain major roof and siding damage. Many shallowly rooted trees will be snapped or uprooted and block numerous roads. Near-total power loss is expected with outages that could last from several days to weeks.
3	111-129 mph 178-208 km/h	**Devastating damage will occur:** Well-built framed homes may incur major damage or removal of roof decking and gable ends. Many trees will be snapped or uprooted, blocking numerous roads. Electricity and water will be unavailable for several days to weeks after the storm passes.
4	130-156 mph 209-251 km/h	**Catastrophic damage will occur:** Well-built framed homes can sustain severe damage with loss of most of the roof structure and/or some exterior walls. Most trees will be snapped or uprooted, and power poles downed. Fallen trees and power poles will isolate residential areas. Power outages will last weeks to possibly months. Most of the area will be uninhabitable for weeks or months.
5	157 mph or higher 252 km/h or higher	**Catastrophic damage will occur:** A high percentage of framed homes will be destroyed, with total roof failure and wall collapse. Fallen trees and power poles will isolate residential areas. Power outages will last for weeks to possibly months. Most of the area will be uninhabitable for weeks or months.

accompanying academic and clinical enterprises. Immediately following Hurricane Katrina, the academic and clinical buildings at Tulane University School of Medicine and Louisiana State University (LSU) School of Medicine were both badly damaged by flood waters.[16] Tulane University collaborated with Baylor University College of Medicine in Houston, Texas to use facilities for its medical student programs. LSU utilized facilities on its flagship campus in Baton Rouge, Louisiana for preclinical classes. Housing for students was a challenge, and most Tulane students were hosted by members of the Houston community, while LSU students either found their own housing in Baton Rouge or stayed on a large ferry coordinated by the Federal Emergency Management Agency. Remarkably, both Tulane and LSU were able to resume medical education within 4 weeks of the hurricane.[16]

Relocating preclinical students proved to be easier than identifying suitable clinical education sites for third and fourth-year medical students. Both schools were forced to find new clinical sites within Louisiana and beyond. Compounding the challenge was the closure of the damaged Veterans Affairs Medical Center in New Orleans. This degree of disruption had an impact on the medical school admissions process for both schools, yet both schools were able to enroll incoming classes very much on par with prior years. With regard to the residency match process, Tulane did experience a slight increase in the number of unmatched medical school graduates, likely owing to the reduction in residency spots at Tulane after the hurricane.[16] Despite all of these formidable challenges, both Tulane and LSU were able to keep their entire medical school enterprises alive, though with some impact on faculty needs. Both institutions were able to improve several physical and academic aspects of their campuses in the years following Katrina. In a sense, these two universities have provided other academic centers with a road map for how to continue to thrive following the harrowing experience of an all-encompassing natural disaster. Their perseverance was essential to the future health care of patients in Louisiana and beyond.

While the medical schools' survival was a triumph, Hurricane Katrina and subsequently Hurricane Rita had a distinctly negative effect on the field of anesthesiology in Louisiana. The two largest teaching hospitals in New Orleans closed after Katrina, and the largest of these—Charity Hospital—never reopened. These closures and other factors led to a decline in the number of anesthesiologists, as documented by a 2006 statewide survey.[17] Statewide residency positions in anesthesiology fell from 24 graduates per year in 2004 to 13 graduates per year in 2007. Like many states, Louisiana is fairly dependent on new anesthesiology graduates remaining in the state to take the place of retiring physicians. Of the respondents, 37% of anesthesiologists reported that they had difficulty filling open positions within their group. In this setting, 92% reported that they had experienced an increase in the number of daily cases, and that obstetric cases for patients with no prenatal care had risen out of proportion to other cases. This phenomenon likely represents a glimpse into the impact of natural disasters on all medical specialties: the same stresses experienced by anesthesiology programs were felt by other residency programs, including the obstetrics and gynecology program. Compared with the complete annihilation of medical infrastructure caused by the earthquake in Haiti, the plight of post-Katrina New Orleans may seem insignificant. Still, the fact that a large city within the wealthiest nation on earth can have its medical infrastructure completely disrupted for months after a storm attests to the impact of large-scale natural disasters.

In September 2017, Hurricane Maria struck Puerto Rico and effectively interrupted the island's access to clean

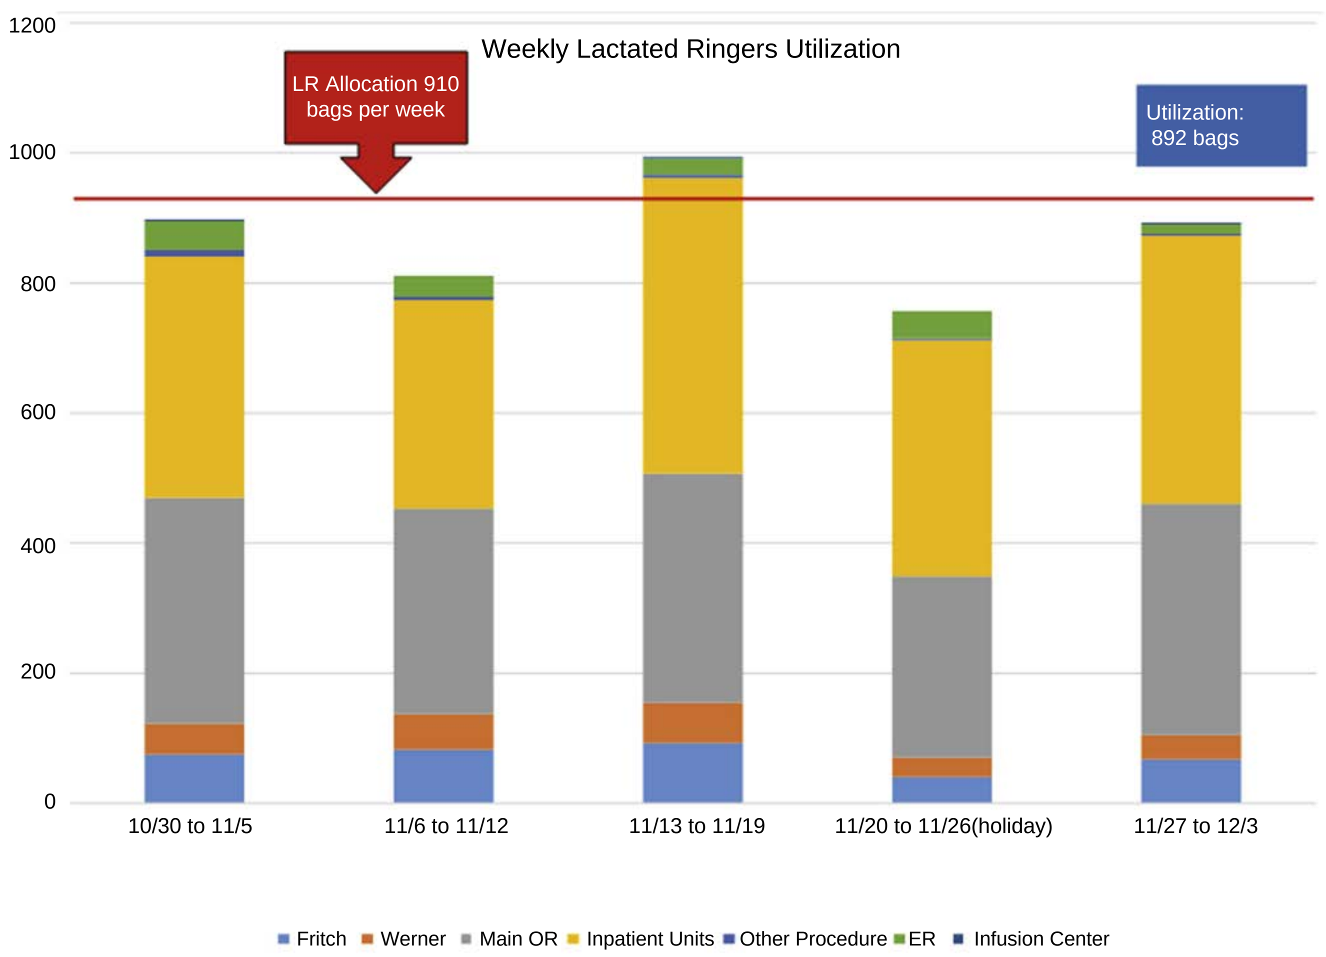

Fig. 68.9 UNMC tracking utilization of lactated Ringers during crystalloid shortage from Hurricane Maria.

water, electricity, telecommunications, and transportation. At the time Maria made landfall on Puerto Rico, it had slightly decreased in intensity from a Category 5 to a Category 4 hurricane, yet it damaged or destroyed nearly every structure in its path and the death toll is estimated by different agencies at between 1000 and 2800.[18,19] Drug and fluid shortages in the continental United States following Hurricane Maria exposed a major vulnerability of the overall healthcare system, and provided anesthesiologists with an opportunity to help lead the way out of a potential nationwide crisis.

Puerto Rico is a massive producer of pharmaceuticals and medical devices. Baxter, a large multinational company had factories in Puerto Rico, producing approximately 50% of all of the 0.9% normal saline bags used each day in U.S. hospitals.[20] The shutdown of these factories, and all other major pharmaceutical factories in Puerto Rico, resulted in an immediate shortage of fluids and medications throughout the United States. The initial response at many mainland hospitals was to identify alternative sources for products in other countries. This approach simply expanded the shortages of fluids and medications internationally.

The experience with shortages of supplies and materials made healthcare leaders recognize the interdependence of all health systems and the importance of conservation of existing supplies and avoidance of waste. In response to the shortages created by the events in Puerto Rico, anesthesiologists at many medical centers were asked to help create strategies to maximize the efficient use of fluids and medications. At the University of Nebraska Medical Center, anesthesiologists worked with other physicians, pharmacists, and leaders in nursing and administration to cocreate robust strategies to avoid critical shortages of necessary fluids and medications. Figs. 68.9 and 68.10 offer a glimpse at some of these strategies. Note that intravenous fluids administered in the operating rooms were required to be on an infusion pump, a major change from the typical "gravity drip" employed by anesthesia providers. The shortages forced healthcare workers across the nation to (1) think more critically about every milliliter of fluid they give to patients, and (2) use different fluids and medications than what they use during times of non-shortage. While the shortages induced by Hurricane Maria were problematic, their net effect has likely been toward positive changes within the U.S. healthcare system. In the aftermath, many have come to realize that our excessive reliance on one U.S. territory for fluids and pharmaceuticals is neither wise nor sustainable.

Section 2: Acts of Terrorism

SEPTEMBER 11, 2001 ATTACKS

On September 11, 2001, an organized team of terrorists commandeered three U.S. airliners with the intention of crashing them into prominent buildings in New York City and Washington, DC. Two of the aircraft were flown directly into the twin towers of the World Trade Center in New York, causing massive fires and eventually causing both of the 110-story buildings to collapse. Nearly 3000 people died as a result of the September 11th attacks, making it the deadliest act of terrorism in recorded history.

An anesthesiologist-intensivist from New York University, Dr. J. David Roccaforte, was on duty at Bellevue Hospital 2.5 miles away from the site of the attack. Dr. Roccaforte's paper describing the hours and days following the 9/11 attack remains essential reading for healthcare professionals in disaster preparedness.[21] In the paragraphs that follow, the key points from this important paper are summarized.

Hospital phone lines were nonfunctional in the hours following the attack, prompting a recommendation that hospitals be equipped with radio communication equipment and satellite-based communication devices. While cellular communication has clearly improved many-fold between 2001 and 2018, it is difficult to predict the performance of modern networks in a situation where millions of users are simultaneously trying to connect with other users. Based on an assumption that hundreds of victims would be arriving rapidly to the operating rooms and EDs, thousands of dollars worth of fluids, medications, and kits were opened and prepared, much of which went to waste. In retrospect, these resources should have been used only with confirmation of patient need. Considering the number of capable hospitals in New York outside of lower Manhattan, a pre-made plan to triage patients from Bellevue and other nearby hospitals out to other trauma centers would have been beneficial. A field hospital was set up in a warehouse near the World Trade Center, intended to be a site for emergency trauma surgery in the event that hospitals were overwhelmed. Unfortunately, the 100-bed field hospital lacked sufficient resources for the provision of anesthesia, and thus was not entirely usable.

Due to the lack of functional telecommunications, medical students were employed as runners and assigned to attending physicians. All workers were encouraged to wear a label on their shirt with name, specialty, and title, to expedite face-to-face communication. While the 9/11 attack did not induce a major failure of the physical plant at Bellevue, the need for hospital engineers was noted. In the event of a failure of electrical or oxygen supply, head engineers would be needed to restore normal state or provide a contingency plan. A traditional triage system using color-coding was used effectively for incoming patients: green signified non-urgent; yellow for potentially urgent; and red for immediate, life-threatening injuries. Any patient in the yellow category with potential need for airway management or sedation was assigned a senior anesthesiology resident or a critical care fellow. As the initial surge of patients slowed, the team at Bellevue wisely mandated a shift system, sending healthcare workers home to rest and avoid the certain burnout that results from ongoing 24/7 care following a major disaster.

MASS SHOOTINGS

In the United States, mass shootings continue to increase in frequency and severity. The Centers for Disease Control and Prevention (CDC) has not been allowed to investigate gun violence as a matter of public health, which has hampered high quality research on this topic. Using a definition of a mass shooting where four or more people are killed by a lone shooter, from 1966 through November 2018 there have been 158 mass shootings in the United States.[22] No region appears to be safe from these events, as they have occurred in schools, churches, offices, and military bases in all parts of the country. The number of people killed in these mass shootings is 1135, with 186 of them being children or teenagers.[22] Accordingly, all anesthesiologists must be prepared to provide care in the aftermath of these heinous events.

The lethality of these attacks appears to be increasing with each passing year, in part because more and more of these shootings are carried out with military-style semiautomatic rifles as opposed to conventional guns. The AR-15 has emerged as the weapon of choice for the criminals who perpetrate these senseless acts. Following the Parkland, Florida, shooting where 17 people were killed by a former student at Marjory Stoneman Douglas High School in February 2018, a radiologist with many years of experience diagnosing gunshot wounds in a Level 1 trauma center penned an article about the drastically different injury pattern visualized with gunshot wounds from an AR-15 versus those from a typical handgun.[23] With a normal gunshot wound, the radiologist can trace a laceration through affected organs that is roughly the same width as the bullet itself. Following the Parkland shooting with an AR-15, radiologists and trauma surgeons observed that tissue had been destroyed in wide swaths near the pathway of bullets. Organs were found to be “smashed” and “shredded,” where traditionally they are found to be merely lacerated following handgun injuries. This extensive damage to surrounding structures occurs as a result of the much higher bullet velocities and thus higher energy levels transmitted by assault rifles as compared with typical handguns.

On October 1, 2017, the worst mass shooting in the history of the United States took place in Las Vegas, Nevada. A lone gunman armed with multiple rifles fired more than 1000 rounds into a large music festival crowd on the Las Vegas strip. His position on the 32nd floor of a nearby hotel and his modification of semiautomatic weapons into automatic weapons likely increased the terrible lethality of the attack. Fifty-eight people were killed and more than 400 were injured by gunfire that night.

In the hours immediately following the mass shooting in Las Vegas, dozens of anesthesiologists were called to respond and provide care for the victims. A friend and colleague, Dr. Devin Kearns, describes the harrowing night:

“I was at home on call for pediatric anesthesia for the Level 1 trauma center here in Las Vegas. Shortly after falling asleep I was awoken by the phone ringing and the familiar voice of my partner. However, this call was anything but routine as he proceeded to say there had been a mass shooting.

The next thing I remember was jumping out of bed while telling my wife there had been a shooting on the strip. As I drove to the hospital I was listening to the radio for updates, not knowing what to expect. Upon arrival I was asked to go to OR 2 and set up for a critically injured, hemodynamically unstable patient who would be arriving shortly. As I checked the machine and prepared medications the situation still seemed surreal. We see a lot of penetrating and non-penetrating trauma at our facility. It is simply part of what we do. But could anything have prepared me for a mass casualty shooting?

As I waited for this critical patient to arrive, the time continued to pass. About 5 or 10 minutes later I called the front desk for an update… the patient didn’t survive.

I then went to the preoperative area and as I entered I witnessed a scene I will never forget. It was a scene I had not prepared for, and a scene I never expected to witness on my soil as I am not a member of the military. I saw multiple fatally wounded patients with their loved one by their side hoping, praying, and longing for the moments prior to the terror and fear they experienced at this senseless act.

Additional victims were triaged as they arrived. We cared for many of them in the operating room and this continued for the days and weeks to follow. These victims were not merely wounded physically, but emotionally, and spiritually as well.”

Dr. Sher’s and Dr. Kearns’ personal accounts of caring for mass shooting victims serve as a reminder to all anesthesiologists. We all must be prepared to provide optimal care for shooting victims with injury patterns that once were limited to military settings. Given the devastating tissue injury induced by assault rifles such as the AR-15, special consideration should be given to obtaining additional vascular access before or during surgery, and to requesting additional blood products prior to losing the tamponade effect following the opening of the abdomen or the chest.

BOSTON MARATHON BOMBING

On April 15, 2013, two homemade bombs made of pressure cookers filled with pellets and nails were detonated 12 seconds apart near the finish line of the Boston Marathon. The unusual nature of the bombs in this incident caused an unusual injury pattern: 3 victims were killed by the blasts and 264 were injured, 66 of whom sustained lower extremity injuries.[24] The close proximity of multiple major trauma centers to the site of the bombing likely played a role in reducing the mortality rate of this event. Despite a collaborative effort among the Boston city trauma centers, EDs were overwhelmed when 78% of the patients treated at city trauma centers arrived within 90 minutes of the initial event. Of these high acuity patients, 45 were admitted directly to operating rooms, 11 to ICUs, and 12 required emergency airway management.[25] Of the 127 patients receiving care at Boston’s trauma centers, over 100 likely had some facet of their immediate care provided by an anesthesiologist. The unique perspective and skills of the anesthesiologists allowed them to provide a wide variety of clinical services within what, in fact, served as the epicenter of terrorism disaster management.

Unlike other terror attacks in the United States, the bombs discharged in Boston caused injuries similar to those observed in the Afghanistan and Iraq wars, caused by improvised explosive devices (IEDs). This injury pattern in wars has prompted a resurgence of interest in the use of tourniquets in the field to prevent exsanguination from major injuries of the extremities.

Of the 66 patients with extremity injuries, 29 of them had life-threatening bleeding at the point of injury.[24] Twenty-seven of these 29 had a tourniquet applied in an attempt to reduce bleeding. All of the 27 tourniquets were improvised, that is, they were not commercially produced tourniquets designed expressly for the purpose of arterial occlusion. The most common type used was rubber tubing wrapped around the extremity combined with a Kelly clamp. Sixty-three percent of the tourniquets were applied by non-emergency medical service (EMS) personnel, and several were not applied tightly enough to actually occlude arterial flow. Experts in battlefield trauma care have discussed the use of tourniquets after the Boston Marathon bombing and have suggested an educational campaign to teach the correct technique for application of purpose-driven tourniquets, and suggested that all EMS providers be provided with these devices. Anesthesia providers have extensive experience with the proper application of arterial tourniquets, as a result of their widespread use during orthopedic operations, so their role is critically important in reducing blood loss and saving lives. In the event of another mass casualty event resulting from IEDs, anesthesiologists, certified registered nurse anesthetists, anesthesia assistants, and anesthesiology residents should instruct healthcare workers and volunteer first aid workers on the application of tourniquets. In the probable absence of purpose-driven commercially produced devices, emergency medicine, trauma, and anesthesia providers should inspect applied tourniquets to ensure they are applied in a manner that will occlude arterial flow.

The two perpetrators of this vicious crime were eventually apprehended and taken to a hospital with severe injuries. One died from his injuries while the other survived. This scenario brings to light one of the challenges of working as an anesthesiologist following a terrorist attack: the physician must continue to provide the best care possible even when the patient has done tremendous harm to other human beings. In situations like this, the physician benefits from focusing on the anatomic and physiologic data at hand, while ignoring the surrounding emotional elements. All physicians must remember their oath to “do not harm,” under any circumstances.

Section 3: Chemical, Biological, Radiological, and Nuclear Warfare

In today’s global political environment the threat of a chemical, biological, radiological, or nuclear (CBRN) attack combined with massive casualties cannot be disregarded. Many people assume that sophisticated and organized individuals initiate these types of attacks; this is not generally the case. Breaking CBRN into two groups, we can see that chemical and biological are more common than radiological and nuclear incidents, which in recent history have been a direct result of natural disasters. Regardless, medical professionals must address, prepare for, and train for these types of disasters and attacks to better care for those negatively impacted. After reviewing the history of CBRN warfare, this section will analyze, define, demonstrate, and outline the U.S. military’s approach to CBRN protocols, procedures, and standard operating procedures (SOPs). Using the structure, function, and focus of the U.S. military’s approach to CBRN will help delineate the anesthesiologist’s role in the civilian sector to help improve patient care while minimizing collateral damage and casualties.

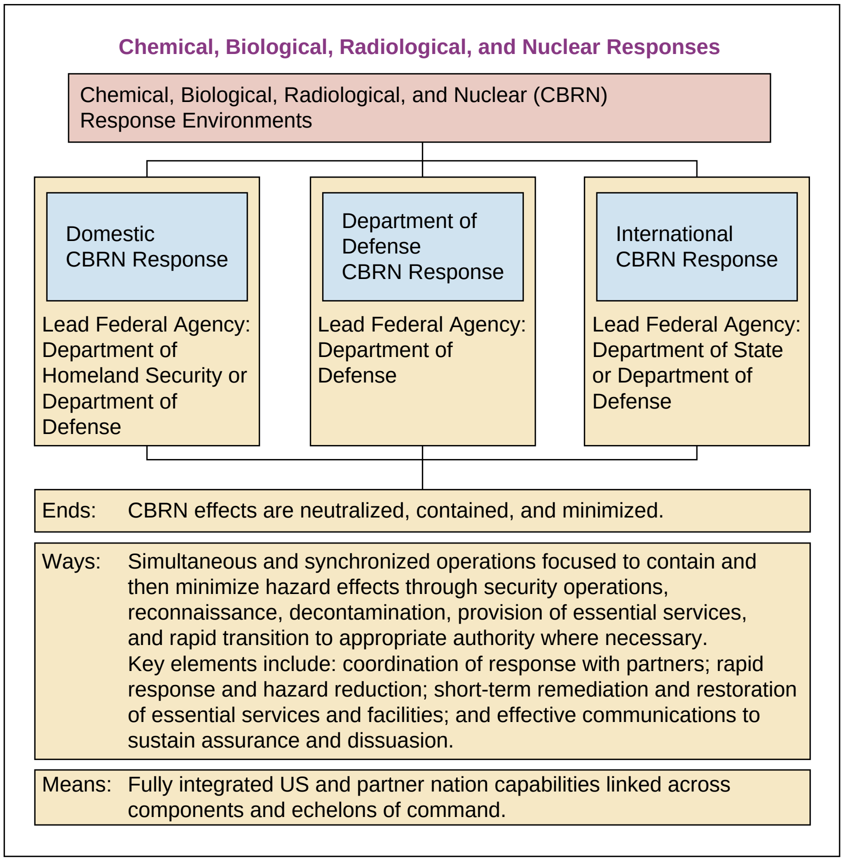
The U.S. military has established a hierarchy, structure, and SOPs for CBRN situations. As acts of terrorism have become more aggressive in recent decades, civilians may be more likely to see the effects and aftermath of a CBRN act of terrorism. Figs. 68.11 and 68.12 outline the Department of Defense (DOD) strategy and hierarchical structure for CBRN attacks on domestic soil, military installations, and abroad.[26] Attempting to adapt the military’s training protocols may help reduce unrest and exemplify the vital role of the consultant anesthesiologist during a CBRN attack.

An increased public awareness of possible CBRN attacks by terrorist groups started in the fall of 2001, when the biological agent, anthrax powder, was mailed to two U.S. senators at their congressional offices in Washington, DC. Civilian medical responders were forced to deal with and experience the toxic effects. As these CBRN terrorist threats have become more apparent toward the civilian populations, anesthesia providers have become more involved with on-site and prehospital medical management. Understanding the toxic effects and pathophysiologic effects of CBRN agents can help reduce the collateral damage to first responders. Anesthesia providers are essential in resuscitation efforts at the scene of an attack and with continued life support measures during sustained CBRN and terrorist attacks.

HISTORICAL ASPECT OF CHEMICAL, BIOLOGICAL, RADIOLOGICAL, AND NUCLEAR WARFARE

Chemical, biological, radiological and nuclear warfare is deeply embedded in the history of world conflicts. The search for tactical wartime and war-fighting advantages have been documented since ancient Babylon. Chemical weapons can be traced back to 10,000 BC when the San society of Southern Africa used natural poisons from snakes on the tips of their spears to hunt antelope. One of the first suspected uses of chemical agents in war can be found between the Persians and Romans in the year 256.[27] According to archeologic evidence, the Persian military exposed Roman soldiers to a noxious gas, killing them before ever having to face them in battle. During the conflict between the Romans and Persians, it was noted that the Persians used a suspected sulfurous gas in a tunnel, quickly killing 20 Roman soldiers by asphyxiation. This primitive form of combusting sulfur crystals in a confined space may have been the very first chemical or biological material employed as an offensive weapon during a conflict. This was centuries before the indoctrination of the Geneva Protocols in 1925, which outlawed the use of weaponized chemicals during wartime.

Biological weapons, and eventually nuclear weapons, have evolved with advancing technologies. In fact, World War I saw the overutilization of chemical agents as offensive weapons. These chemical agents included phosgene gas, chlorine gas, and mustard gas during the infamous trench



Chemical, Biological, Radiological, and Nuclear Responses
Chemical, Biological, Radiological, and Nuclear (CBRN) Response Environments
Domestic CBRN Response
Lead Federal Agency: Department of Homeland Security or Department of Defense
Department of Defense CBRN Response
Lead Federal Agency: Department of Defense
International CBRN Response
Lead Federal Agency: Department of State or Department of Defense

Ends: CBRN effects are neutralized, contained, and minimized.

Ways: Simultaneous and synchronized operations focused to contain and then minimize hazard effects through security operations, reconnaissance, decontamination, provision of essential services, and rapid transition to appropriate authority where necessary.
Key elements include: coordination of response with partners; rapid response and hazard reduction; short-term remediation and restoration of essential services and facilities; and effective communications to sustain assurance and dissuasion.

Means: Fully integrated US and partner nation capabilities linked across components and echelons of command.

Fig. 68.11 U.S. Dept. of Defense CBRN Response table. (Adapted from Joint Publication 3-41, Chemical Biological, Radiological and Nuclear Response, September 9, 2016.)

warfare encounters between 1915 and 1918. Chemical weapons were very effective and the release of these gases during battle had substantial impact and accounted for a large number of casualties (Figs. 68.13 to 68.15). These heinous attacks against unprepared troops led to chemical and biological weapons being considered weapons of *mass destruction* by the British government, because they led to catastrophic and painful loss of life. During World War I, more technologically advanced chemical and biological weapons continued to be used, resulting in approximately 1.3 million casualties related to these explosive devices.[28] This is why many historians consider World War I as the “Chemist’s War.” The toxic effects of chemical weapons during World War I were compounded by the fact that many of these weapons were combined with ballistic explosive shells to increase lethality of the chemicals. The combination of toxin and ballistic injuries led to compounding casualties on and away from the battlefield, as a consequence of the crippling nature of the chemical weapons on those that survived the chemical attacks.

There have been historical attempts to prevent and outlaw these weapons of *mass destruction* due to a review of legal implications of chemical and biological weapons. It started in 1899 with the Hague Declaration Concerning Asphyxiating Gases and again in 1907 at the Hague Convention on Land Warfare, which actually outlawed the use of poison or poisoned agents during wartime.[29] In this regard, the actions and implementation of chemical and biological agents during World War I violated these regulations. However, the landmark international regulation of 1925 in Geneva outlined, outlawed, and made the use of chemical weapons a crime against humanity, which nearly led to a cessation of chemical and biological weapons development as history moved forward toward World War II.

Under very tight secrecy, a major discovery by the German scientist Gerhard Schrader in 1936 led to the invention of anticholinesterase nerve agents. These nerve agents were not utilized in World War II, but they became more of a threat afterwards. In 1945, the former Soviet Union captured a major nerve agent manufacturing plant, subsequently giving the Soviet Union not only nuclear capabilities but biochemical weapons for mass destruction.[30] The most unfortunate aspect of the Soviet seizure of this manufacturing plant was that the Soviet military leaders began to see chemical, biological, and nerve agents as normal armaments for war. This philosophy was contrary to the Geneva convention and the worldwide ban on chemical and biological weapons.

Several other countries have been implicated in secret development and advancement of chemical and biological weapons. Most notably, the Chinese and Japanese governments denied reports of developing weapons of mass destruction, but since 1930 they have been suspected of researching and manufacturing chemical and biological weapons.[31] Unfortunately, these biological agents were tested on prisoners and the general population without proper consent, which is considered a crime against humanity under the Geneva Conventions.[32] This secret

testing went on for years without notice by other world powers. Even though this is a vile and awful act against the general population, substantial research data were collected. After the capture of one of the project leaders by the United States, considerable intelligence was passed to the federal government regarding this chemical and biological research. This formed the basis for the United States' offensive biological and chemical weapons research and development as a response to other countries stockpiling these weapons. However, the Biological Weapons Convention in 1972 put an effective stop to worldwide research and stockpiling of chemical, biological, and nerve agents for weaponization.[33]

Despite the 1972 Biological Weapons Convention putting an enormous price on continued chemical, biological, and nerve agent research, the Soviet Union continued to manufacture and stockpile weapons of mass destruction. The Soviet biological warfare program hit a peak in the mid-1970s, when they developed a whole new type of biological weapon and weapon systems. The former Soviet Union's government denied these programs existed and the fact that these weapons' systems had been deployed around the world as a first strike weapon.[34] Again, continued chemical and biological weapons research was considered an inhumane act of war, but during the cold war some research actually focused on antidote-based chemical regimens to aid and manage wounded combatants. Unfortunately, with the deployment of chemical, biological, and nerve agents as offensive weapons around the world, it also contributed to these weapons being transferred to terrorist groups because of decreased accountability for these weapons by the end of the Cold War.

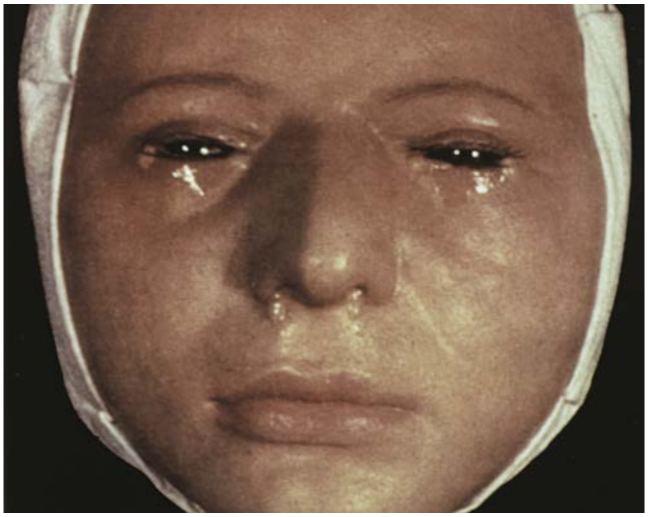

Fig. 68.14 Eye injury caused by mustard gas. (Courtesy Her Majesty's Stationery Office, London, United Kingdom.)

The 1980s saw a shift to chemical and biological weapons as a true first-line offensive weapon. At this point in history, chemical and biological injuries could be treated more effectively on the battlefield and by first responders on the civilian side. The research into antidotes for chemical, biological, and nerve agents had finally caught up to their weaponization. The United Nations had documented the combined uses of vesicants and nerve agents, such as mustard gas and tabun toxin to increase the lethality of chemical and biological weapons.[35,36] These agents were not as effective as expected, and they accounted for only about 27,000 Iranian casualties, or about 1% of the total casualties of the Iran-Iraq war. The noted reason for the ineffectiveness or decline in lethality of these chemical weapons can be accounted for by the research into antidotes and improved care on and around the battlefield. In contrast to the organized battlefield during the Iran-Iraq war, when this agent was released on a civilian population of Halabja in Iraqi Kurdistan, it accounted for more than 5000 deaths, or a large percentage of the Kurdish village population.[37] This contrast in lethality demonstrates the improvement to battlefield medicine as well as the effectiveness of the antidotes.

The last part of the 20th century saw several civilian attacks utilizing different combinations of chemical, biological, and/or nerve agents. In one of the most notorious nerve agent attacks in Tokyo, Japan, sarin gas was used in the subway system and was responsible for multiple fatalities and injuries. Unfortunately, during this mass casualty experience, civilian medical personnel lacked knowledge, training, and understanding of appropriate medical treatments and became casualties themselves.[38,32] The lack of training for civilian medical providers and emergency staff brought home important lessons for all, especially anesthesia providers. Box 68.1 outlines the lessons learned from this nerve agent attack.[32]

Despite the progressive weaponization of chemical, biological, and nerve agents over many decades, classifying them appropriately can be challenging. In the simplest terms, they can be classified as weapons of *mass destruction*, but the application of that term was short-lived because of the advancement of antidotes and improved medical treatment. By definition, weapons of mass destruction have to have a significant destructive impact on a society, such as the atomic bombs dropped on Hiroshima and Nagasaki, Japan. In regards to chemical, biological, and nerve agents, they are defined by their effects on the populations on which they have been released, and many of these devices lack the large explosive component as compared to nuclear weapons: true weapons of mass destruction.[31] In the 1950s, because of the Tizard report, chemical, biological, and nerve agents were to be included within the term "weapons of mass destruction." In this report, the term weapon of mass destruction referred solely to the massive loss of life the weapon was capable of creating. Overall, regardless of the mechanism and explosive power of the weapon employed, chemical, biological, nerve agents, and nuclear isotopes are all considered very lethal threats to society. This holds true regardless of whether they are classified as weapons of mass destruction. The massive release of chemical, biological, or nerve agents among a very large population is possible in theory, but this would require a delivery modality such as a missile, rocket, or violent explosive vehicle.[31]

BOX 68.1 **Tokyo Sarin Gas Lessons Learned for First Responders**

Lesson 1	Military-grade chemical, biological, and nerve agents can be easily employed by terrorist groups
Lesson 2	HAZMAT and incidence management training for chemical, biological, and nerve agent mass causalities was not sufficient
Lesson 3	Lack of situational (scene) control, protection, and personnel decontamination contributed to additional casualties and fatalities
Lesson 4	Lack of resuscitation efforts at the site of chemical and biological release contributed to further casualties
Lesson 5	This incident lead to a significant database for medical management of patients exposed to nerve agents

CHEMICAL, BIOLOGICAL, RADIOLOGICAL, OR NUCLEAR HAZARDS DEFINED

Chemical

Historically, chemical agents were purely a military issue, because there were only a small number of people with access or knowledge to chemical agents or weapons. However, over the past 20 years the types of chemical hazards have expanded significantly because of the advanced use of toxic chemicals required for industrial manufacturing. Chemical hazards are chemicals that can cause death or harm because of their toxic properties. The characteristics of the most commonly talked about chemical agents are discussed in Table 68.2.

Most chemical agents, whether industrialized or weaponized, have the ability to severely incapacitate a person or cause immediate or imminent death. Chemical agents begin their onset of physiologic symptoms when the body comes in contact with a concentration of agent that is more than one's body can tolerate. As an anesthesiologist, traumatologist, or first responder, one must be able to rapidly identify the difference between mild and severe symptoms of chemical agent exposure, which are outlined in Table 68.3. The main categories of chemical agents are outlined here:

1. Blistering agents (vesicants)—Generally affect the eyes and mucous membranes. In addition, they damage the respiratory epithelium. Airway management in these patients can be cumbersome for anesthesia providers because of sloughing off epithelium and necrotic tissue occluding the glottic view and anatomy.[40] Overall, the effect and toxicity depend on the type of agent, the concentration of the agent, the weather/weather patterns, and exposure time.
2. Blood agents (nerve agents)—Generally inhibit oxygen transfer from blood or hemoglobin to the cells of the body, or in another way causes tissue hypoxemia. Overall, the higher the concentration of blood agents, the more rapidly fatal these agents are. Most blood agents inhibit acetylcholinesterase activity, increasing the concentration of acetylcholine at the muscarinic and nicotinic receptors, causing cholinergic toxicity.[41] This excessive acetylcholine in the body can cause a myriad of symptoms, but for the anesthesiologist airway interventions can be hindered because of

TABLE 68.2 Most Commonly Discussed Chemical Weapon Agents

Name	Type	Properties	Mechanism of Action	Physiologic Symptoms	Onset of Action
Sarin gas	Nerve	Colorless, odorless, volatile	Anticholinesterase agent	Choking, miosis, headache, nausea, respiratory distress, convulsions, death	Minutes
VX (VR) gas	Nerve	Colorless, odorless, oily liquid	Anticholinesterase agent	Choking, miosis, headache, nausea, respiratory distress, convulsions, death	<30 min
Mustard gas	Blister	*Garlic odor*, oily liquid	Vesicant, bone marrow suppression, alkylating agent, damages deoxyribonucleic acid	Blisters skin, eyes, lungs	~4-6 h
Cyanide gas	Blood	*Almond odor*, volatile	Interferes with oxygen utilization at the cellular level	Hinders oxygen transfer, *respiratory paralysis*	Minutes

significant airway occlusion from secretions and profound bronchospasm, which is why atropine should be administered prior to any airway intervention.[12,42,43] Higher concentrations of agent lead to more rapid physiologic decline proceeding to cardiopulmonary arrest.

3. Choking agents (pulmonary agents)—Generally cause a shift of fluid into the small airways at lower doses, while at higher doses all the major airways become irritated and dried out, causing choking, poor gas exchange, and ultimately, death. Rapid, shallow breathing, painful cough, and cyanotic skin are indicative of fluid filling the lungs and preventing oxygenation. Commonly, these patients will present with pulmonary physiology that mimics acute respiratory distress syndrome because of the fluid shifts, airway irritation, and inflammation.
4. Riot control agents—Generally cause lacrimation or vomiting. Unlike the choking agents, they are irritants that are used to cause a brief period of misery and harassment to subdue or incapacitate a threat or aggressive persons. Most of these agents inhibit multiple different enzymes and invariably increase bradykinin release.[16] Overall, these agents do not require significant medical attention except flushing of the eyes and removal from the environment.

Biological

Biological hazards are relatively easy to produce, especially since production facilities have very little environmental signature. Production of these microbes or organisms can pose a significant threat to human and animal welfare. Biological agents differ from chemical agents in that the agents are living organisms, viruses, toxins and/or microtoxins utilized to disable, disrupt, or kill other human beings or other organisms. While most biological agents are small, they have tremendous potential for lethality and application to a large-scale attack. Most biological agents are accessible throughout the world and are relatively inexpensive to produce compared to weaponization of chemical, radiological, or nuclear agents. Today's most commonly discussed biological agents are orders of magnitude stronger and more lethal than most chemical agents. These agents are outlined in Table 68.4. A common limitation of many biological agents is that they can be degraded by changes in the environmental conditions such as ultraviolet light, temperature, and humidity.

Many of the initial symptoms of biological warfare and a biological attack are vague and nonspecific. However, in the event there is high index of suspicion for a biological attack, steps must be taken to protect first responders and medical personnel. Physical protective barriers and personal protective equipment (PPE) are essential primary preventive measures. In addition, for other hazard responders and personnel there are vaccinations and immunizations for certain biological agents. By protecting our primary responders and healthcare providers during biological attacks, they are more apt and readily able to care for those directly and immediately in danger. PPE and these concepts will be explored in more detail in the Epidemic and Pandemic Infectious Outbreaks section.

TABLE 68.3 Typical Chemical Agent Exposure Symptoms

Mild Symptoms*	Severe Symptoms†
Runny nose	Sudden confusion
Sudden severe headache	Wheezing, labored breathing
Drooling	Miosis
Blurry vision	Painful tearing eyes
Chest pain	Sudden profound vomiting
Difficulty breathing	Severe muscle twitching/seizures
Sweating	Uncontrolled urination
Muscle twitching/cramps	Uncontrolled defecation
Stomach cramps	Profound respiratory difficulties
Nausea	

*Some symptoms of chemical agent intoxication can be confused with severe heat stroke.

†Adapted from the Multi-Service Doctrine for Chemical, Biological Radiological and Nuclear Operations (FM 3-11, MCWP 3-37.1, NWP 3-11, AFTTP 3-2.42).

Radiological and Nuclear Weapons and Effects

Radiological hazards include electromagnetic or particulate radiation capable of causing damage, injury, or destruction through ionizing effects of neutrons, γ rays, α particles, or β particles. Radiological damage can be dispersed in many ways, but ultimately causes destruction, damage, or injury to a large population of people, while exposing an even larger population to the lingering effects of ionizing radiation.

Nuclear weapons are a complete assembly of weapons capable of independently being armed, fired, fused, and detonated to release a large-scale nuclear explosion capable of significant destruction to the land, environment, people, and animals within a large area. The intensity of nuclear weapons is greater than that of chemical and biological weapons, and the deployment of a nuclear weapon will cause significantly more death and destruction from the point of detonation, outward. Short- and long-term devastation can be attributed to nuclear fallout, which is the residual radioactive material that is propelled into the atmosphere following a nuclear detonation. Thus, nuclear and radioactive material is literally falling from the sky and is moved miles and miles away by winds within the atmosphere.[44]

Unlike chemical attacks or biological attacks, nuclear/radiological attacks rarely induce the need for immediate airway intervention, even in the harshest of exposed patients. While nuclear warfare can devastate a large area, the immediate impact can be considered similar to a high-grade explosive device. The main difference between nuclear weapons and conventional explosives is that a nuclear weapon will do greater damage by orders of magnitude. Overall, acute management of the effects of high radiation doses is prudent. Most commonly, supportive care of the hematological, gastrointestinal, neurologic, cardiovascular, and integumentary systems are required. Following a major radiological or nuclear attack, patients with significant nausea and vomiting may require intubation for airway protection.

Mass Casualty Situations and Chemical, Biological, Radiological, or Nuclear Attacks

Overall, the structure, function, and focus of the U.S. military's approach to CBRN can be adapted to the civilian sector wherever feasible to help improve patient care while minimizing collateral damage. All CBRN incidents are emergency situations that require multi-system coordination and organization. Table 68.5 demonstrates the sources and types of CBRN hazards. There are three basic reasons why CBRN situations occur:

TABLE 68.4 Most Commonly Discussed Weaponized Biological Agents

Common Name	Agent	Physiological Effects	Onset
Anthrax	*Bacillus anthracis*	Fever, fatigue, severe respiratory impairment, high fever, and excessively rapid pulse rate. Pulmonary anthrax is fatal more than 90% of the time.	1-5 days
Plague	*Yersinia pestis*	Fever, headache, and rapid heart rate, followed by pneumonia and hemorrhage of the skin and mucous membranes. Untreated plague pneumonia fatalities approach 100%, but early treatment can reduce mortality to as low as 5%.	2-3 days
Tularemia	*Francisella tularensis*	Fever, chills, headache, and muscular pain. Untreated tularemia can result in 30%-60% mortality; treated, mortality rate is reduced to 1%.	3-5 days
Botulism	*Clostridium botulinum*	Extreme weakness, nausea, headaches, and intestinal pain leading to respiratory paralysis that may cause death.	2-26 h

1. Intentional—This is a deliberate action to induce harm in the form of toxic agents, release of radiological agents, or the detonation of explosive material in an attempt to cause terror for political, religious, or ideological purposes.
2. Accidental—A human error–induced release of toxic agents, release of radiological agents into the environment, or detonation of explosive material.
3. Natural—Caused directly by or in response to a natural disaster, which leads to the release of toxic agents, release of radiological agents into the environment, or detonation of explosive material.

Currently the American Society of Anesthesiologists (ASA) has several suggested protocols for CBRN attacks, but to make these protocols most useful will require extensive and ongoing training. Disaster preparedness and coordination is not simply an ED problem to manage. For anesthesia providers, it is critically important to reinforce clinical skills and practices so that, in the event of a massive casualty event, during a natural disaster, or during a potential CBRN attack they are prepared to respond immediately and appropriately. Box 68.2 outlines the basic CBRN rules all providers should follow during a CBRN attack. Many providers do not have the adequate training to support a mass casualty situation and this leads to increased unrest and disorder. In civilian hospitals, training for CBRN as an

BOX 68.2 CBRN Basic Provider Rules and Guidelines for Safety

Rule 1	DO NOT become the casualty yourself
Rule 2	Always decontaminate the scene, situation, and patient prior to any movement to the Operating Room
Rule 3	Never assume ANY vaccine is 100% protective
Rule 4	"SAFE ZONES" should always protect themselves from contaminated "WALK-INS"
Rule 5	We all make mistakes, when in doubt call infectious disease, the CDC or WHO
Rule 6	Always decontaminate the casualties, then immediately begin ACLS, ATLS, and resuscitation measures to stabilize patients
Rule 7	Pay careful attention to sterile techniques, many patients will have compromised immune systems and/or already be neutropenic
Rule 8	Brain irradiation can cause all sorts of primary, secondary, and tertiary CNS symptoms
Rule 9	Ionizing radiation victims are less of a risk to providers compared to chemical/biological casualties

ACLS, Advanced cardiac life support; *ATLS*, advanced trauma life support; *CDC*, Centers for Disease Control and Prevention; *WHO*, World Health Organization.

entire unit is extremely challenging, because it is almost impossible to shut down an entire hospital for a day or several hours to properly practice, train, and prepare. The U.S. military, their military hospitals, and healthcare personnel have required unit, battalion, and command training exercises on U.S. soil and abroad for CBRN attacks, which help maintain order, direction, and patient care during times of turmoil and civil unrest.

Incident Management During a Chemical, Biological, Radiological, or Nuclear Attack and Personal Protective Equipment

In the face of a mass casualty event from a CBRN attack, panic and chaos are to be expected. Successful response to a CBRN attack requires command and control personnel and the medical providers to prioritize the following: personnel safety, personnel protection, command establishment, and site-wide communication. Similar to the U.S. military, the civilian sector has command control entities in the form of local, state, and federal response systems. Once the command structure is established for the incident in question, the commander is directly responsible for directing and controlling all available resources.

The first rule for CBRN casualty treatment and maintenance states, "Do not become the casualty yourself". The incident commander or officer in charge is in charge of setting the protection level to ensure maximal barrier protection and adequate PPE for all providers and first responders. Unfortunately, the appropriate PPE level to use may not be immediately known, so it is advantageous to err on the side of a higher protection during immediate decontamination and stabilization efforts. The U.S. military has adapted their PPE levels from the U.S. Environmental Agency's *Hazardous waste operations and emergency response* protocols.[45] At any time during intubation, exposure to bodily fluids, and/or airborne infection the minimum protection level should be C. In addition to this protection level, in an unknown CBRN attack all medical examinations for severe casualties or those severely and negatively impacted by the CBRN attack should be done per Table 68.6.

Protection is the key feature of incident management, and anesthesia providers should be familiar with several levels of PPE suits and masks, and the techniques of decontamination in Table 68.7. Several levels of protection are used in the management of toxic releases, but the appropriate level for medical intervention is level C, which allows reasonable tactile dexterity and contact with the patient to provide essential life support and antidote therapy onsite.[46] Level C protection is equivalent to that used by the military to provide protection against the most toxic chemical warfare agents and virulent biological warfare organisms.[47]

TABLE 68.6 Initial Workup for Severely Injured Casualties During Chemical Biological, Radiological, or Nuclear Attack

Investigation	Lab Test/s
Urea and Electrolytes	▪ Arterial blood gas ▪ Glucose ▪ Lactate ▪ Calcium/phosphorus/magnesium
Full Blood Count	▪ Store sample for later analysis ▪ Consider coagulation/clotting studies
Urinalysis	▪ Store for later analysis
Electrocardiogram	
Chest Radiogram	

Store all blood samples in a safe containment area for personnel protection and for future analysis.

TABLE 68.7 Levels of Personal Protective Equipment in Chemical, Biological, Radiological, or Nuclear Incidents[45]

Level	Minimum Personal Protective Equipment Required
A	▪ Positive pressure SCBA ▪ Fully encapsulated chemical-resistant suit ▪ Double layer of chemical-resistant gloves ▪ Chemical-resistant boots ▪ Airtight seal between suit and gloves and boots
B	▪ Positive pressure SCBA ▪ Chemical-resistant, long-sleeved suit ▪ Double layer of chemical-resistant gloves ▪ Chemical-resistant boots
C	▪ Full-face air-purification device (respirator) ▪ Chemical-resistant suit ▪ Chemical-resistant outer gloves ▪ Chemical-resistant boots
D	▪ Equipment does not provide specific respiratory or skin protection and usually consists of regular work clothes

SCBA, Self-contained breathing apparatus.

Decontamination

In most situations the initial hazards are unknown, however protecting oneself is one of the major keys to on-scene and in-hospital care of the afflicted patients. Many hazards are short-lived or transient, but it should be assumed that the hazard released is persistent and transmissible through the on-scene decontamination zones. Immediately establishing the level of personal protection required for medical staff, paramedics, and ancillary search and research personnel by the on-scene commander is vital to preventing an increased number of casualties among medical and rescue personnel. To safely work on search and rescue and decontamination many on-scene commanders immediately place a level C minimum for PPE for medical staff and paramedics, and upgrade or downgrade based on situational changes onsite. Triage personnel and medical personnel are vital to providing immediate: (1) triage, (2) life-support measures (TOXALS—toxicology advanced life support), and (3) antidote and other pharmacologic support.

Early life-support measures in the decontamination zone are very important.[48,49] A unique perspective to CBRN on-scene decontamination and resuscitation was introduced in 1996, and was uniquely termed TOXALS (Toxicology Advanced Life Support) to be used in conjunction with advanced cardiac life support (ACLS), advanced trauma life support (ATLS), and basic life support (BLS) in the setting of chemical, biological, and/or radiological attacks. TOXALS protocol expands the on-scene and in-hospital resuscitation efforts of trained medical personnel. and incorporates principles of ACLS, ATLS, and BLS, which can be expanded to the pneumonic ABCDDEE: airway, breathing, circulation, disability, drugs, exposure, and environment.

Summary of Chemical, Biological, Radiological, or Nuclear Section

CBRN attacks and natural disasters have similar elements to medical care on the battlefield. Population control, situational control, and on-scene containment are essential to maintaining order and functionality of the civilian emergency disaster system. As anesthesiologists, the main responsibility is to be present for operating room needs, but their advanced medical knowledge, advanced pharmacology knowledge, and advanced trauma-stabilization training makes them ideal to aid and support emergency triage physicians. Not all patients during CBRN attacks or natural disasters immediately go to the operating room for stabilization. Many of the emergency responders and providers will need support either in triage, for ED consultations, pain management, or intensive care support for stabilization, pharmacology expertise, and/or procedural skills. For example, a small roving team consisting of an anesthesiologist, a critical care/ED nurse, and a respiratory therapist could manage a wide variety of critically injured patients following a CBRN massive casualty event.

An anesthesiologist's primary role is to stabilize and ensure safe operating conditions for casualties of any CBRN attack, terrorist attack, or natural disaster. However, this is not limited to preoperative assessment and intraoperative management of CBRN victims. During times of crisis, anesthesiologists cannot remain sequestered in the operating room awaiting the arrival of injured patients. They must be proactive within the hospital system or emergency response system, providing triage and management of patients prior to arrival at the operating room or the ICU.

Section 4: Epidemic and Pandemic Infectious Outbreaks

Until recently, the role of anesthesiologists in biological disasters, such as infectious epidemics and pandemics, had been discussed only in the most general terms. While the lifesaving application of positive pressure ventilation by Danish anesthesiologist Dr. Bjorn Ibsen probably saved hundreds if not thousands of lives during the Copenhagen polio epidemic of 1952, the role of North American anesthesiologists as critical members of the management team in biological disasters was not fully exploited until the severe adult respiratory syndrome (SARS) epidemic of 2003 and the West African Ebola epidemic of 2014.[50-52] During both of these worldwide healthcare crises, anesthesiologists not only played critical roles as caregivers, but risked personal safety when functioning in their role as specialists in airway management and intensive care. Knowledge of the disease, management options, and importantly, infection-control measures necessary to protect oneself, are all critical for anesthesiologists to contribute maximally and mitigate personal vulnerability during the next epidemic or pandemic.[53]

Health emergencies in the form of regional epidemics and global pandemics have the capacity to kill more than 10 million people across continents and around the world.[54] While this number sounds excessive and perhaps even alarmist, it is in fact a conservative estimate when compared to pandemics over past centuries. Smallpox is the deadliest pandemic in human history. In the 20th century alone, estimates of deaths due to smallpox exceeded 300 million people with 30% of all persons infected succumbing to the disease.[55] The causative agent, Variola virus, is thought to date back possibly as far as 3000 years to the time of the Egyptian Empire. Its global spread paralleled the advance of modern civilization, exploration, and expanding trade. Thanks to the success of worldwide vaccination, the last person to die of smallpox was in 1978 and on May 8, 1980 the 33rd World Health Assembly officially declared the world smallpox free.[56,57] Unfortunately, unlike viruses that have a human reservoir such as smallpox, polio, and measles, and hence are targets for eradication, the next pandemic is more likely to be the result of zoonotic transmission.[58]

PANDEMIC INFLUENZA A

Past influenza pandemics have occurred when genetic mutations in an enzootic cycle result in re-assortment of gene segments creating what is functionally a novel infectious agent with major changes in surface proteins, capable of sustained human-to-human transmission in a global population with little existing herd immunity.[59] Pathogenic influenza A viruses arising from this antigenic shift have been the source of influenza A pandemics for centuries. In fact, there have been no less than 10 pandemic influenza A events over the past 300 years.[60] In the preceding century alone, there were three episodes of pandemic flu. A recent analysis of the "Spanish Flu" H1N1 pandemic of 1918 to 1919 estimated that at least 50 to 100 million people died worldwide. Less severe, but also with considerable mortality (approximately 1 million globally; 100,000 in the United States), were the 1957, "Asian Flu" H2N2 and the 1968 "Hong Kong Flu" H3N2 (Fig. 68.16).[60,61] Such events underscore the pandemic threat posed by avian influenza viruses, emphasizing the need for advanced preparation necessary to augment both the clinical and research response to future global health emergencies. In fact, given the incidence and variety of influenza viruses circulating in zoonotic populations, a virus possessing the necessary properties to cause a pandemic can emerge any time.[62]

In 2009, the world experienced the first major influenza A event of the 21st century. This worldwide influenza outbreak has been described by the CDC as the 2009 H1N1 Pandemic. The virus contained a unique combination of influenza genes not previously identified in animals or people. The genes were most closely related to North American swine and Eurasian swine H1N1 influenza viruses. Because of this, initial reports referred to the virus as a swine influenza virus. However, it quickly became apparent that this new virus was circulating among humans and not among U.S. pig herds. In the United States, there were over 60 million cases over the course of a year from April 2009 to April 2010. Fortunately, loss of life attributable to this event was relatively limited with an estimated 12,500 lives lost in the United States and 284,000 globally.[63,64]

Central to disaster planning for pandemic flu is an understanding of the strategies to minimize transmission of influenza between patients and healthcare workers. Despite vast clinical experience, there is still debate over how influenza is transmitted. Possible modes of transmission included in past discussions are airborne, droplet, and contact transmission. Each requires a different infection control approach and almost certainly different PPE. Recent analysis of multiple human and animal studies concluded that natural influenza transmission in human beings occurs over short distances primarily via droplet and contact routes.[65] Transmission of influenza virus via large-particle droplets generated from the respiratory tract of infected individuals during coughing, sneezing, talking, or during procedures such as suctioning or bronchoscopy requires close contact between the infected source and the recipient (6 feet or less). Large droplets do not remain suspended in the air and hence special ventilation or airflow systems are not required since true aerosolization does not occur. Preferential airborne transmission has not been documented as a method of human-to-human influenza transmission.[66] However, many procedures such as intubation and bronchoscopy have the potential to be aerosol-generating. The current literature does not define conditions under which influenza could become opportunistically airborne. Given the paucity of data in this regard, it may be reasonable to employ airborne precautions and higher levels of PPE such as N95 masks when such events are medically necessary. This is important information for anesthesiologists caring for potential flu victims in the ICU or managing their airway in the emergency room, hospital ward, or operating room.

SEVERE ACUTE RESPIRATORY SYNDROME

Severe acute respiratory syndrome (SARS) caused by a novel coronavirus, called SARS-associated coronavirus (SARS-CoV), was first reported in Guangdong Province in China in November 2002. The first case appears to be a businessman from the city of Foshan who subsequently died from the disease. However, it was 3 months later, when a physician from the same province became ill while staying in a hotel in Hong Kong, that SARS rose to international attention. Twelve guests staying at the same hotel subsequently became infected, including seven whose rooms were on the same floor as the physician. These hotel guests became the index patients transporting the virus around the globe as they traveled home by airplane. While SARS was first identified in Toronto, Canada, in March, 2003, because of the speed of international travel, in less than 4 months about 4000 cases and 550 deaths from SARS could be traced to the guests infected in Hong Kong. Ultimately, a total of 8096 people in 29 countries became infected with SARS-CoV, of which 774 of them died (Table 68.8).[67-69]

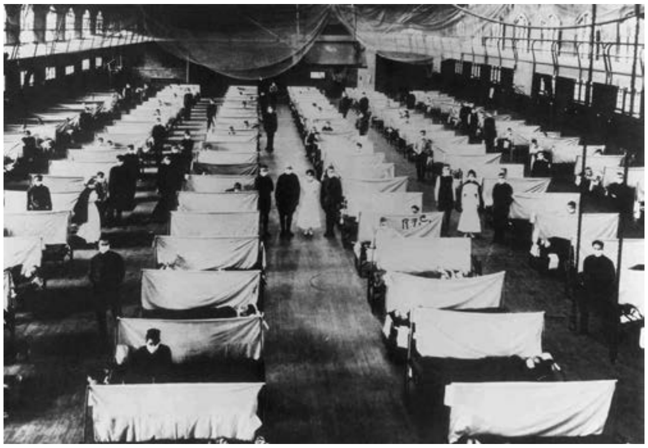

Fig. 68.16 Mass care of patients during 1918 flu pandemic. (From Clements BW, Casani J, eds. *Disasters and Public Health: Planning and Response, Second edition*. Oxford: Butterworth-Heinemann (Elsevier); 2016.)

Toronto was the epicenter of the disease in North America. The Ontario Ministry of Health reported 361 SARS cases, including 33 deaths (9%). Over half of those infected were healthcare workers including three anesthesiologists and one intensivist.[10,27,53,70] Overall case fatality was approximately 15%, but over 50% for patients over the age of 65.[9] On July 4, 2003, the World Health Organization (WHO) announced the global SARS outbreak was contained.[71]

SARS, like influenza, is of zoonotic origin. The virus is ubiquitous and has been isolated from swine, cattle, dogs, cats, and chickens. In 2002, SARS-CoV was isolated from Himalayan palm civets found in Chinese live animal markets where demand for freshly killed meat and poultry served as the source of SARS-CoV crossing species (Fig. 68.17).[72] This led to culling of the animals, although subsequent studies have not validated infection in either farm-raised or wild civets. More recent data suggest that bats are the more likely natural reservoirs of SARS-like coronavirus.[73]

Spread largely by droplets and direct contact, the virus demonstrates tropism to multiple organs and has been found not only in the lung, but the liver, kidney, sweat glands, parathyroid, pituitary, pancreas, adrenal glands, and the brain. As such, the disease is considered a true systemic illness with both pulmonary and extrapulmonary manifestations amplifying opportunity for healthcare worker exposure. This is important for anesthesiologists, intensivists, and other healthcare workers as viral shedding may occur not only in respiratory secretions but stool, urine, and even sweat.[72] Appropriate PPE providing protection beyond droplet and contact precautions is indicated when caring for SARS patients.

MIDDLE EAST RESPIRATORY SYNDROME

Like SARS, Middle East respiratory syndrome (MERS) is caused by a novel coronavirus, MERS-CoV. The first two cases of MERS-CoV infection as a cause of community-acquired pneumonia were first identified in Saudi Arabia and reported to the WHO in September 2012. As of September 2018, laboratory-confirmed cases of MERS number 2260 with 803 associated deaths (35.5%) in 27 countries across the globe.[74,75] The

TABLE 68.8 Mortality of Severe Acute Respiratory Syndrome Based Upon Age

Age (Years)	Mortality
<24	<1%
24-44	6%
45-64	15%
>65	>50%

Modified from Peng PW, Wong DT, Bevan D, et al. Infection control and anesthesia: lessons learned from the Toronto SARS outbreak. *Can J Anaesth*. 2003;50(10):989–997.

majority of cases have been reported in Saudi Arabia, United Arab Emirates, and the Republic of Korea (South Korea), although over 80% of reported cases to date have been linked to exposure in Saudi Arabia (Fig. 68.18).[76]

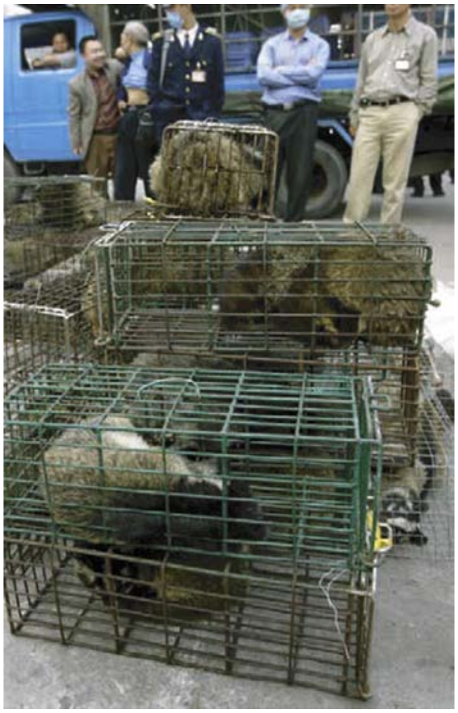

Fig. 68.17 Live animal markets are the interface where animal to human inter-species transmission of SARS-CoV occurred. Guangzhou government officers seize civets in Xinyuan wildlife market in Guangzhou to prevent the spread of SARS-CoV. (From Lau YL, Peiris JS. Pathogenesis of severe acute respiratory syndrome. *Curr Opin Immunol.* 2005;17[4]:404–410.)

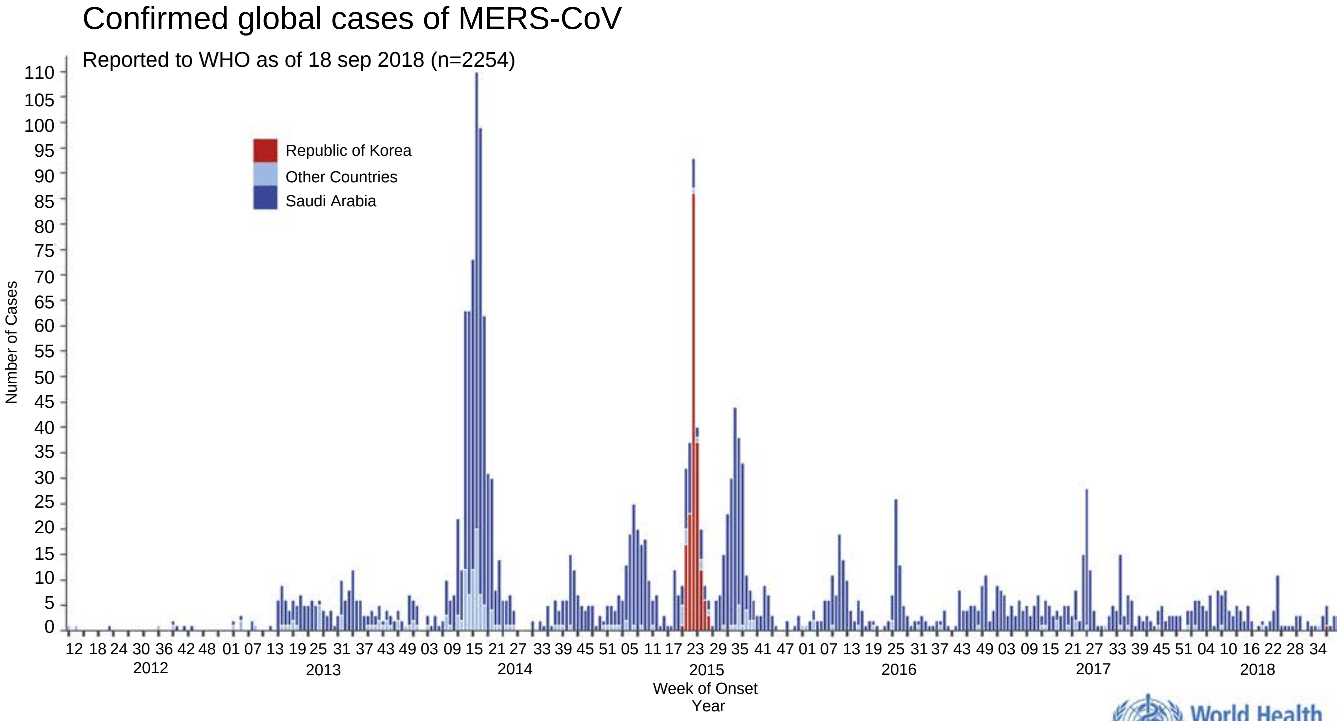
MERS-CoV, like SARS-CoV, is a zoonotic virus. Dromedary camels appear to be the major reservoir host and animal source of MERS infection in humans through either direct or indirect contact. The specific method of transmission remains unclear, but poorly cooked camel meat and unpasteurized camel milk remain suspect, and consumption of raw or undercooked animal products carries a high risk of infection. Human-to-human contact in the non-healthcare setting appears rare with little to no sustained human-to-human transmission documented.[77]

Human-to-human transmission through close contact within the healthcare setting accounts for the majority of reported cases to date. Outside of Saudi Arabia, the largest outbreak so far occurred in South Korea in 2015.[77] In a hospital-associated cluster, a single infected person admitted to a hospital in South Korea led to 186 cases and 36 deaths across multiple healthcare facilities.[78,79] This particular case highlights the consequences of substandard infection control practices and inadequate use of PPE, as the virus does not pass easily person to person unless there is close contact.[76] Healthcare workers must remain alert for the continued threat of MERS as global travel continues to accelerate.

EBOLA VIRUS DISEASE

Ebola virus disease (EVD) is a zoonotic disease affecting people and non-human primates. The presumptive enzootic reservoir is believed to be African fruit bats, although this cause is still not definitive. Ebola is an RNA *Filovirus* and a member of the *Filoviridae* family. There are five species of Ebola virus, of which four are pathogenic to humans. The most common and possessing the highest case fatality rate (60%-90%) is the *Zaire ebolavirus*. *Sudan ebolavirus, Taï Forest ebolavirus, Bundibugyo ebolavirus* also are pathogenic to humans, but



Other countries: Algeria, Austria, Bahrain, China, Egypt, France, Germany, Greece, Iran, Italy, Jordan, Kuwait, Lebanon, Malaysia, Netherlands, Oman, Philippines, Qatar, Thailand, Tunisia, Turkey, United Arab Emirates, United Kingdom, United States of America, Yemen
Please note that the underlying data is subject to change as the investigations around cases are ongoing. Onset date estimated if not available.

at lower fatality rates. The *Reston ebolavirus* while known to cause disease in nonhuman primates and swine, has not been indicted as a cause of human disease.[80] Marburg virus, the first known *Filovirus* was first described in 1967. Both viruses are known to cause viral hemorrhagic fever in humans with high fatality rates. The higher fatality rate of EVD makes it an important biothreat pathogen and, given the severity of recent outbreaks, worthy of more detailed discussion.[81,82]

Historically, the virus has been isolated to rural regions of Sub-Saharan Central Africa. EVD outbreaks have occurred relatively frequently over the past 30 years since the first outbreak in 1976 alongside the Ebola river in the village of Yambuku, Zaire, in what is now the northern Democratic Republic of Congo and South Sudan.[83] Ultimately, two genetically distinct species of virus were isolated bearing the names of their respective geographic areas.[81] In 2014, the beginnings of what would become the largest outbreak of EVD on record took hold in West Africa. On March 21, 2014, the WHO was notified of a growing outbreak in southeastern Guinea. The disease spread quickly to its capital, Conakry, and then to the neighboring countries of Liberia and Sierra Leone.[82] West Africa had never experienced an EVD outbreak and given the socio-economic conditions of these nations, was poorly equipped to respond. By the time the outbreak was declared over in June of 2016, there were 28,610 cases and 11,308 deaths for a mortality rate of 39%. To put things in perspective, from 1976 to 2014 there were fewer than 2500 cases reported worldwide (Table 68.9).[84]

The Ebola virus is transmitted through contact with infected secretions. Ebola has been identified in blood, saliva, vomit, feces, urine, sweat, nasal secretions, semen, and genital secretions. There is no evidence of airborne spread. Ebola enters the host through mucosal surfaces or

breaks in the skin.[82] This route of transmission reinforces the necessity of appropriate PPE use for all healthcare workers. Once in the body, the incubation period is anywhere from 2 to 21 days. The mean incubation period in the 2014 epidemic was noted to be 11.4 days and did not vary by country.[85] The most common symptoms reported between symptom onset and case detection included fever (87.1%), fatigue (76.4%), loss of appetite (64.5%), vomiting (67.6%), diarrhea (65.6%), headache (53.4%), and abdominal pain (44.3%). The most prominent feature in the 2014 outbreak was the progression of the gastrointestinal symptoms and resultant dehydration, severe electrolyte disorders, acute kidney injury, hypoperfusion, systemic inflammatory response syndrome, and shock (Table 68.10).[83,85] Capillary leak syndrome becomes profound in the late stages of the disease and rarely can be associated with respiratory distress. Preterminal events include decreased level of consciousness, which can progress to seizure and coma, disseminated intravascular coagulation, hepatic necrosis, renal failure, and gastrointestinal hemorrhage. Nonsurvivors succumb to multiorgan failure refractory to supportive care.[82,83,85,86]

During the West African Ebola outbreak, 11 people received treatment for EVD in the United States. A total of three patients brought from West Africa to the United States experienced multiorgan failure requiring mechanical ventilation and renal replacement therapy. One patient lived and two died. Care was provided in specialized biocontainment units (Fig. 68.19). Advanced life-sustaining therapy was managed at Emory University Hospital, Serious Communicable Disease Unit; at the University of Nebraska Medical Center—Nebraska Medicine, Nebraska Biocontainment Unit; and at Texas Health Presbyterian Hospital Dallas. All three patients were male and presented with severe gastrointestinal symptoms including severe diarrhea and multiorgan dysfunction notable for respiratory, cardiovascular, renal and hepatic insufficiency. Two patients were encephalopathic. All had extremely high viral loads. Of the two patients that died, the last 12 hours of life was characterized by refractory lactic acidosis and abdominal distension suggesting gastrointestinal perforation or ischemia.[51,87]

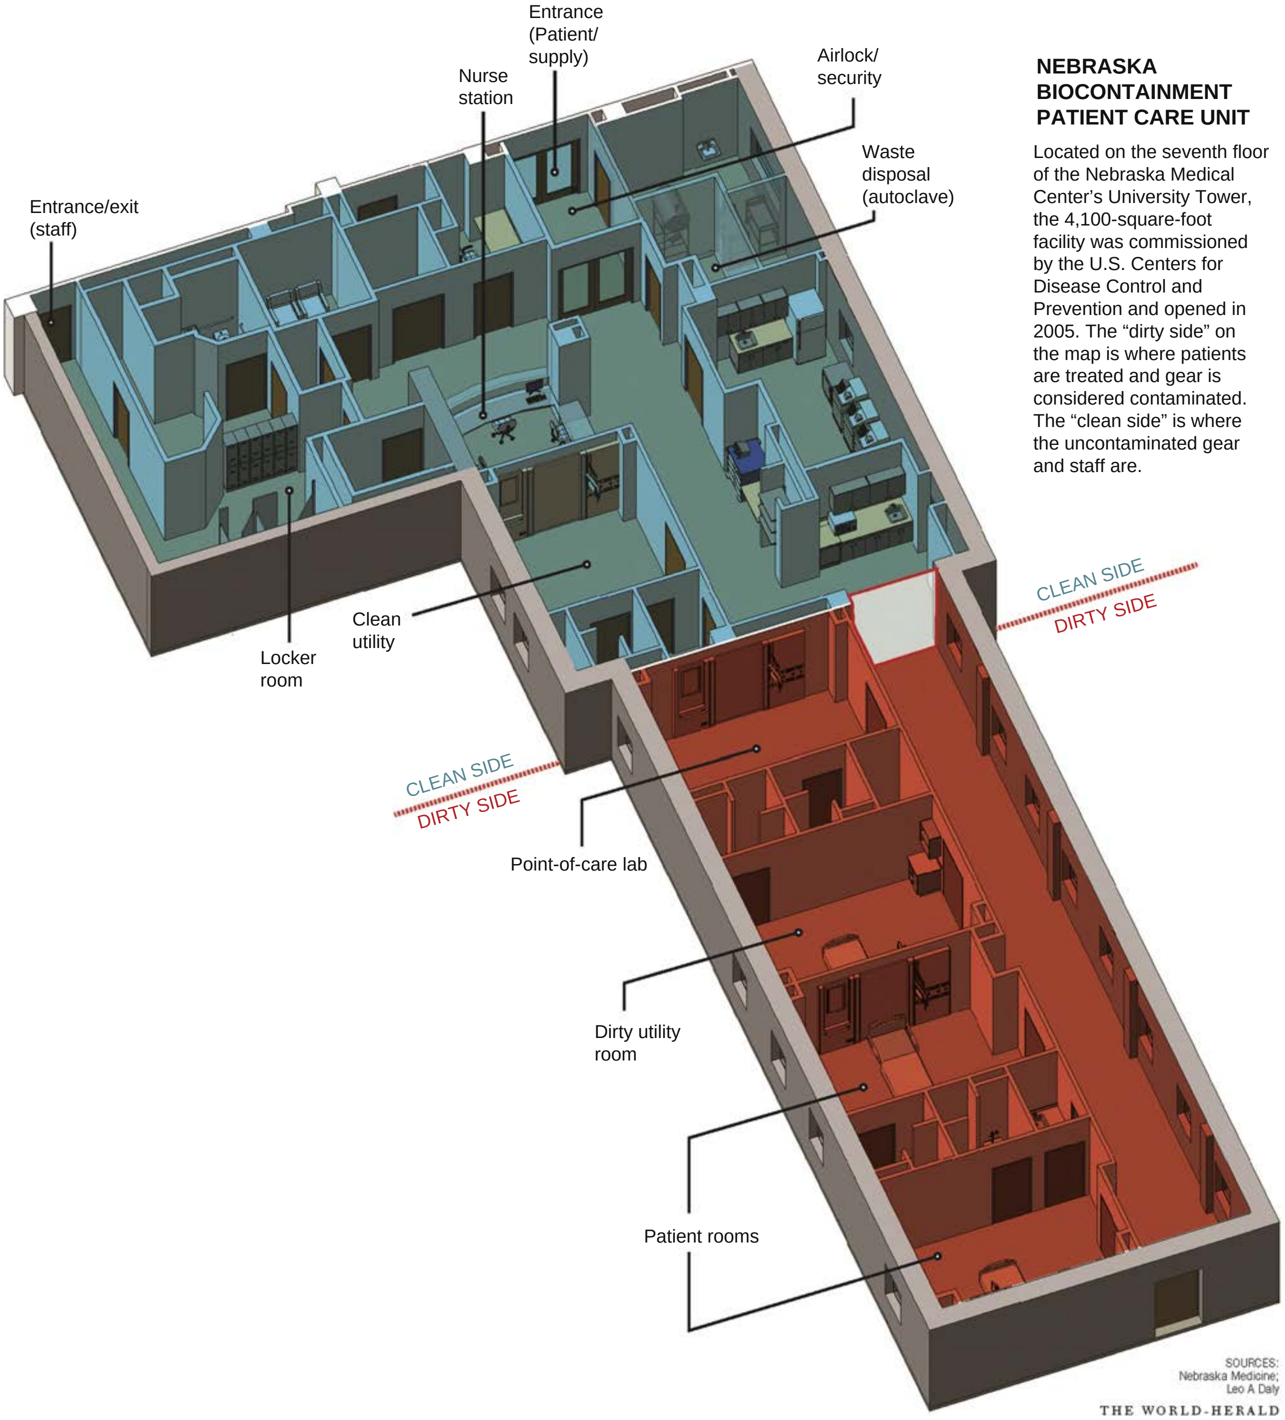
The 2014 West African Ebola outbreak is notable for the fact that approximately 27 patients with EVD have now been cared for in resource-rich settings. Signs and symptoms of EVD at the time of presentation to a hospital in the United States or Europe were similar to those presenting to Ebola treatment centers in West Africa. Mortality when care was provided in Europe or the United States was 18.5%. This is significantly better than mortality of patients in the more resource-challenged environment of the West African Ebola treatment units (37%-74%) and the historic mortality of 66%.[84,88] That said, EVD remains a fatal disease despite full access to advanced life support, modern diagnostic and laboratory support, and aggressive ICU care. Also notable is the fact that critically ill patients who have survived have presented early in the continuum of the disease. While no one can assume early support translates to better outcomes, the first-world experience with EVD suggests that early intervention may improve outcomes.[87]

PERSONAL PROTECTION

The logistics of caring for patients with disease due to highly contagious pathogens is complex and outside of the scope of this chapter as is a detailed discussion of PPE. That said, it is relevant to note some consistencies which are likely to reduce human-to-human transmission whether patient-to-patient or patient-to–healthcare worker. More important than the unique physical structure of the units located in the United States and Europe within which patients with highly communicable diseases receive care is the culture of safety and preparedness, including the critical importance of training healthcare workers to care not only for the patient, but for themselves as well.[89] As noted, the Ebola virus is a highly infectious pathogen. The infectious dose is fewer than 10 virus particles. Given that blood viral titers can exceed 10^8 virus particles per milliliter, it is not surprising that even highly trained healthcare workers have become infected.[88,90]

Those providers caring for patients on hospital wards, in the operating room, and in the ICU have the highest risk of contracting the disease themselves. This is reflected in the experience with the SARS-CoV, MERS-CoV, and, of course, the Ebola virus. In all situations, patients become infected and, in some cases, die as a result of lack of appropriate training and a lack of the critical knowledge specific to the pathophysiology of each disease as well as the logistics of caring for patients while protecting oneself.[89]

While adherence to standard infection control universal precautions is advisable when caring for all patients, anesthesia providers who have close contact to oral and respiratory secretions need to pay particular attention to elements of hospital protocols that apply to patients with respiratory infections or the risk thereof. In addition to precautions necessary to prevent contact routes of transmission vis-à-vis



NEBRASKA BIOCONTAINMENT PATIENT CARE UNIT
Located on the seventh floor of the Nebraska Medical Center's University Tower, the 4,100-square-foot facility was commissioned by the U.S. Centers for Disease Control and Prevention and opened in 2005. The "dirty side" on the map is where patients are treated and gear is considered contaminated. The "clean side" is where the uncontaminated gear and staff are.
Entrance (Patient/ supply)
Nurse station
Airlock/ security
Waste disposal (autoclave)
Entrance/exit (staff)
CLEAN SIDE
DIRTY SIDE
Clean utility
Locker room
CLEAN SIDE
DIRTY SIDE
Point-of-care lab
Dirty utility room
Patient rooms

hand hygiene, gloves, and gowns, droplet precautions should be in place for all patients with suspected or confirmed influenza, SARS, or MERS. At a minimum, providers should be wearing a facemask when entering the room of a patient with suspected influenza, including perioperative areas such as the preoperative holding area or postanesthesia care unit. When moving a suspected influenza patient on droplet precautions from one area of the hospital to another, having the patient wear a facemask during transport is prudent. This would of course include transport to and from the operating room if deemed medically safe and appropriate.[66]

Anesthesiologists routinely perform medical procedures that are aerosol-generating in patients with highly contagious pathogens such as discussed above. We should only perform procedures on patients with suspected or confirmed disease that are critical to optimizing care. As an example, for Ebola patients, centrally or peripherally inserted catheters should not be placed for hemodynamic monitoring, but rather only for critical vascular

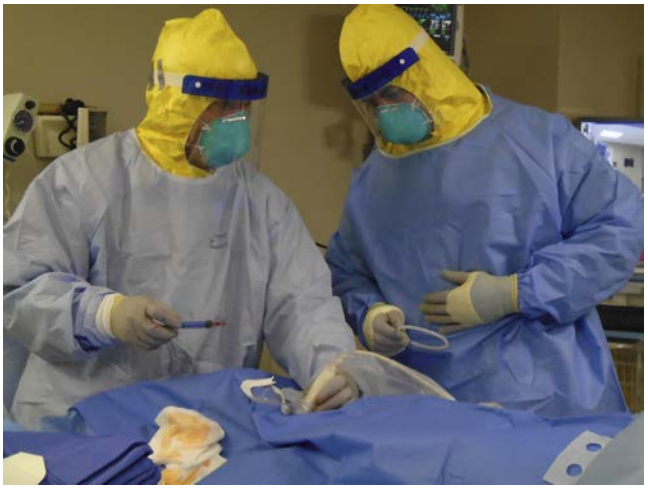

Fig. 68.20 Anesthesiologist placing ultrasound guided central venous line in the Nebraska Biocontainment Unit.

access from which to obtain blood samples without the need for repeated needlesticks and to administer fluids, electrolytes and vasoactive medications. Similarly, when considering respiratory support, early intubation may be preferable despite the inherent risk of aerosolization when compared to noninvasive positive pressure ventilation (NIPPV) and the risk of vomiting, hematemesis, and or aspiration. NIPPV may also result in aerosolization of fluids containing viruses putting caregivers at excess risk not only from Ebola, but also from other highly contagious diseases. Arterial lines should be placed in the upper extremity whenever possible and avoid placement in a femoral artery site due to the potential risk of fecal soiling of the line (Fig. 68.20).[51,80] If intubation is necessary, having a carefully predetermined plan for semi-elective non-emergent intubation is essential. Some of the issues to address to minimize complications associated with intubation include ensuring availability of all medications that may be required and access to all likely equipment that might be needed to secure the airway. In addition, depending on the level of biologic precaution necessary, providers must accommodate for the time necessary to don appropriate PPE prior to entering the patient-care environment.

Finally, all healthcare staff must be instructed to review and understand the guidelines for personal protection appropriate for each pathogen. Certainly, when caring for Ebola patients, the minimum level of PPE should include disposable water-resistant suit or coverall, including a hood; an N95 mask; a disposable full-face shield; two sets of gloves (appropriately sealed), and impermeable foot and leg coverings. It is highly recommended that the addition of a powered air purifying respirator be included when providers are doing any medical procedure with high risk of aerosolization.[51,82] Doffing of PPE is perhaps the highest-risk moment for unrecognized contamination with Ebola virus. For this reason, the entire doffing process should be strictly supervised by a doffing partner. The doffing partner should have no other role besides supervising the healthcare worker who is removing PPE (Fig. 68.21).

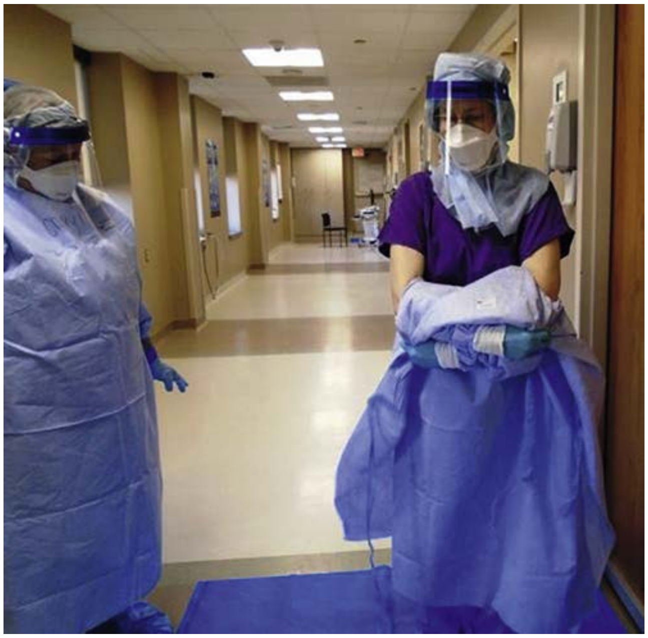

Fig. 68.21 Strict supervision of the personal protective equipment doffing process by a dedicated doffing partner in the Nebraska Biocontainment Unit.

Acknowledgment

The editors and publisher would like to thank Dr. David J. Baker for contributing a chapter on this topic in the prior edition of this work. It has served as the inspiration for the current chapter.

Anesthesia for Ophthalmic Surgery

ZHUANG T. FANG, ELAINE CHIEWLIN LIEW, and MARY A. KEYES

KEY POINTS

- Ophthalmic procedures are considered to be "low-risk." However, the patient population is higher risk because of the extremes of age involved and associated comorbidities.
- Some ophthalmic surgeries (cataract, glaucoma, simple vitrectomy) are short procedures, but high in volume. The demand for efficiency while maintaining patient safety is a challenge.
- The majority of ophthalmic procedures can be performed under topical anesthesia or orbital block in combination with monitored anesthesia care (MAC).
- A working knowledge of the anatomy and physiology of the eye is essential in providing safe anesthesia care. This includes the effect of anesthetic drugs and interventions on intraocular pressure and systemic effects of ophthalmologic medications.
- Orbital blocks, particularly retrobulbar blocks, can have severe complications, including retrobulbar hemorrhage, and retrograde spread of local anesthetic into the subarachnoid space causing brainstem anesthesia, loss of consciousness, and respiratory arrest.
- Routine preoperative laboratory testing is not necessary for cataract surgery and has not been shown to reduce adverse perioperative events.
- General anesthesia is required in 30% to 40% of ophthalmic surgeries. This includes pediatric ophthalmic surgery; complex procedures, some of which require muscle relaxation; and adults who cannot undergo MAC for a variety of reasons.
- Strabismus surgery is an independent risk factor for postoperative vomiting in pediatric patients.
- Succinylcholine can be used in unfasted patients who have an open-globe injury that requires emergent vision-saving surgery under general anesthesia.
- Prevention of prolonged postoperative anesthesia care unit stay and unanticipated hospital admission requires careful patient evaluation, optimization of underlying medical conditions, adequate pain control, prevention of postoperative nausea and vomiting, and maintenance of hemodynamic stability.

Overview of Ophthalmic Anesthesia

Vision is one of the most important functions of the human body. Visual impairment and blindness limit a person's ability to function normally in daily living,[1-3] has a large economic impact in the United States, and results in significant loss of quality-adjusted life years.[4,5] Currently, about 4.2 million adults in the United States are visually impaired.[6] Early diagnosis and treatment, including surgery, can potentially reverse vision impairment, such as in cataract extraction, or delay and attenuate the pathophysiological process, as in glaucoma and diabetic retinopathy. Anesthesia providers specialized in ophthalmic anesthesia play an important role in helping patients undergo surgery comfortably and safely.[6]

Ophthalmic surgeries are the most common operations performed in the elderly.[7] They consist of a broad spectrum of procedures, ranging from cataract surgery with minimal sedation to more complex procedures such as orbital decompression, or combined corneal transplantation and retinal surgery that requires general anesthesia. The majority of ophthalmic surgeries are short in duration and primarily performed in ambulatory surgical centers. Patients who undergo ophthalmic surgery can be as young as preterm infants to nonagenarians. Ophthalmic procedures are generally considered low risk because they do not cause significant physiological perturbations, and do not involve a large volume of blood loss or significant postoperative pain.[8] However, ophthalmic surgery is often carried out in elderly patients who have a high prevalence of coexisting illnesses such as diabetes, hypertension, coronary artery disease, and chronic obstructive pulmonary disease. Adequate preoperative evaluation and optimization are important in the prevention of same day cancellation and unplanned hospital admission.

Patient safety is paramount in ophthalmic anesthesia. In the American Society of Anesthesiologists (ASA) Closed Claims Project from 1980 to 2000, the identifiable causes of severe eye injury include intraoperative patient movement, either under general anesthesia or monitored anesthesia care (MAC), and needle trauma related to an orbital block with or without patient movement.[9,10] In an ASA closed claims analysis of injury and liability associated with MAC for ophthalmic and nonophthalmic surgeries, the major mechanisms of injury included inadequate oxygenation or ventilation, cardiovascular event, equipment failure, inadequate anesthesia leading to patient movement, and oversedation leading to death or permanent brain damage.[11] Presently, there is little data available regarding postoperative complications associated with ophthalmic anesthesia. A retrospective study of prolonged postanesthesia care unit (PACU) stay following ophthalmic surgery found the incidence was about 0.6%,[12] with the major factors being hypotension, bradycardia, postoperative nausea and vomiting (PONV), and oversedation. A similar study found new onset cardiac dysrhythmia, pain, PONV, and pulmonary-related events (hypoxia and pulmonary aspiration) were the main reasons for unintended hospital admission with an incidence of 0.23%.[13] Overall, ophthalmic surgery is safe with a low incidence of anesthesia-related complications.

Fast-track surgery has been successfully implemented in ophthalmic surgery to facilitate early discharge home and to allow patients to resume normal activities of daily living.[14] Each patient's anesthetic plan should be personalized based on the type, duration, invasiveness of surgery, underlying comorbidities, degree of anxiety, expectation of anesthesia, and history of anesthetic complications with the goal of "fast-tracking" and minimizing potential adverse events postoperatively. Perioperative surgical home is a patient-centric, team-based model of care to improve population health, reduce costs, and satisfy patients.[15] It can improve outcome[16] and may be a useful model in ambulatory surgery settings, including ophthalmic surgery.

Patient satisfaction has become a standard indicator of value in health care, including anesthesia care.[17,18] For ophthalmic surgery, information, communication, pain control, comfort, and support are the most important predictors for patient satisfaction in the perioperative period.[19,20]

OCULAR ANATOMY

The eye is a delicate and complex organ that allows us to see images, color, and movement, and helps with depth perception and balance. The eye is a sphere measuring approximately 24 mm in diameter. It is situated in the pyramidal bony orbit. The wall of the globe has three layers: the sclera, the uveal tract, and the retina. Fig. 69.1 shows the individual components of the eye.

The sclera is the outermost layer. It is the tough, fibrous white of the eye, and it is continuous with the cornea anteriorly. The tissue where the cornea and sclera meet is the limbus, which contains stem cells responsible for regeneration of the epithelium. About 60% of the focus power of the eye is from the curvature of the cornea.

The middle layer, the uveal tract, has three structures: the choroid, the iris, and the ciliary body. The choroid is a layer of blood vessels located posteriorly. Bleeding in this layer is one cause of intraoperative expulsive hemorrhage. The pigmented iris controls light entry with muscle fibers that change the size of the pupil. Sympathetic stimulation dilates the pupil by causing iris dilator muscles to contract, whereas parasympathetic stimulation causes meiosis, or pupillary constriction by causing the iris sphincter muscles to contract. The ciliary body lies just behind the iris; it produces aqueous humor. Ciliary muscle fibers adjust the focus

by releasing tension on the suspensory fibers, or zonules, of the lens. Opacification of the lens causes a cataract. Uveitis is an inflammatory condition of these structures (iris, choroid, and ciliary body).

The innermost eye layer is the retina, which is a membrane consisting of highly specialized nerve tissue continuous with the optic nerve. Light stimulates retinal photoreceptors to produce neural signals that the optic nerve carries to the brain. There are no capillaries in the retina; the choroid layer provides oxygen and nourishment to the retina. Retinal detachment from the choroid layer compromises the retinal blood supply and is a major cause of vision loss. The retinal layer ends approximately 4 mm behind the iris. The area between the limbus of the cornea and the retina is called the *pars plana*. Because there is no retinal layer there, it is a safe entrance site for vitrectomy procedures.

The center of the eye is filled with vitreous gel. This thick fluid has attachments to blood vessels and the optic nerve. Traction of the vitreous on the retina is a cause of retinal detachment. Scarring, bleeding, or opacification of the vitreous is treated by vitrectomy.

The extraocular muscles move the globe within the orbit. They arise from a fibrous ring near the apex of the orbit and insert on the sclera. The six extraocular muscles lie within a cone behind the eye surrounding the optic nerve, ophthalmic artery and vein, and ciliary ganglion.

The eyelids have an outer layer of skin, a muscle layer, a tarsal plate of cartilage, and a layer of conjunctiva. The conjunctiva is a mucous membrane that lines the inner eyelids and covers the globe up to the corneal-scleral junction.

The lacrimal gland sits in the superior temporal orbit. It releases tears across the surface of the globe. Tears drain via the puncta near the medial canthus of the eyelids. Tears flow through the canaliculi to the lacrimal sac and duct, to drain into the nasopharynx.

The ophthalmic artery provides most of the blood supply to the orbital structures. It is a branch of the internal carotid artery, close to the circle of Willis. The superior and inferior ophthalmic veins drain directly into the cavernous sinus.

Cranial nerves (CN) innervate the ocular structures. The optic nerve (CN II) carries the neural signals from the retina. The oculomotor (CN III), trochlear (CN IV), and abducens (CN VI) control the extraocular muscles. Touch and pain sensations are carried via the trigeminal nerve (CN V). Sensation to the lower lid is via the maxillary nerve (CN V_2). Sensation to the upper lid is via the frontal branch of the ophthalmic nerve (CN V_1). The nasociliary branch of the ophthalmic nerve sends sensory fibers to the medial canthus, lacrimal sac, and ciliary ganglion.

The ciliary ganglion provides sensory innervation to the cornea, iris, and ciliary body. Parasympathetic fibers originate from the oculomotor nerve (CN III) and synapse in the ciliary ganglion before supplying the iris sphincter muscle. Sympathetic fibers originate from the carotid plexus and travel through the ciliary ganglion to innervate the dilator muscle of the iris. Local anesthetic blockade of the ciliary ganglion produces a fixed, mid-dilated pupil.

The facial nerve (CN VII) exits the base of the skull from the stylomastoid foramen. It supplies motor innervation to the orbicularis muscle via the zygomatic branch. Local anesthetic block of the facial nerve can prevent lid squeezing.

OCULOCARDIAC REFLEX

The oculocardiac reflex was first described by Aschner and Dagnini in 1908. It is also known as the *trigeminovagal reflex*. Traction on the extraocular muscles or pressure on the globe causes bradycardia, atrioventricular block, ventricular ectopy, or asystole. In particular, it is seen with traction on the medial rectus muscle, but it can occur with stimulation of any of the orbital contents, including the periosteum. The response fatigues with repeated stimulation.

The afferent of the reflex limb arises from the ophthalmic division of the trigeminal nerve and continues to the Gasserian ganglion and the sensory nucleus of the trigeminal nerve near the fourth ventricle. Here, the afferent limb synapses with the motor nucleus of the vagus nerve. The efferent impulses travel to the heart via the vagus nerve leading to decreases in both heart rate and contractility of the heart.

The reflex may be seen more often with procedures performed with topical anesthesia, and it occurs commonly in pediatric patients undergoing strabismus surgery. Retrobulbar block is not uniformly effective at preventing the reflex. Orbital injections can also trigger the response. The response is exacerbated by hypercapnia or hypoxemia.[21,22] In the event of arrhythmia, the anesthesiologist should first ask the surgeon to stop manipulations. Any condition that may exaggerate the reflex such as hypoxia, hypercapnia, and an inadequate depth of anesthesia should be assessed and treated. If significant bradycardia persists or recurs, intravenous glycopyrrolate or atropine can be given. Rarely, epinepherine is given to treat severe bradycardia or asystole. Rarely, epinephrine is given to treat severe bradycardia or asystole.

INTRAOCULAR PRESSURE

Normal intraocular pressure (IOP) is 16 ± 5 mm Hg and a value in excess of 25 mm Hg is considered pathological. Normal IOP is necessary to maintain cornea curvature and a proper refracting index of the eye. The intraocular perfusion pressure, defined as the difference between the mean arterial pressure and the IOP, is part of the system regulating blood perfusion to the eye's internal structures. High IOP impairs the blood supply, leading to a loss of optic nerve function.

The globe is a relatively noncompliant compartment. The volume of the internal structures is fixed except for aqueous fluid and choroidal blood volume. The quantity of these two factors regulates IOP. 80% to 90% of aqueous formation occurs through active secretion by the ciliary body mediated by Na-K ATPase and carbonic anhydrase enzymes. The remainder is from passive filtration and ultrafiltration across the ciliary epithelium. It then enters the angle of the anterior chamber to flow through the trabecular meshwork into the Schlemm canal and the episcleral veins. IOP is primarily regulated by the resistance at the trabecular meshwork.[23]

Impairment of aqueous drainage at any point can elevate the IOP. Sclerosis of the trabecular meshwork is believed to cause the chronic pressure elevation in open-angle glaucoma. Closed-angle glaucoma occurs when there is an obstruction to aqueous drainage from closure of the anterior chamber angle. This happens from peripheral iris swelling or anterior displacement. Patients with a preexisting narrow angle may be predisposed to this condition. The acute increase in pressure causes severe pain and is an ophthalmologic emergency.

Anesthetic drugs and the conduct of anesthesia have important effects on IOP. All volatile anesthetic drugs cause a decrease in IOP.[24-26] Nitrous oxide (N_2O) has no effect on IOP. The commonly used intravenous induction anesthetics such as propofol, thiopental, and etomidate all reduce IOP, with propofol causing a moderate reduction in IOP even when used as low-dose intravenous sedation.[27] Ketamine does not increase IOP (see the section Anesthesia for Pediatric Ophthalmology). The mechanism by which anesthetic drugs reduce IOP is not fully elucidated but involves depression of central nervous system ocular centers, resulting in relaxation of extraocular muscle tone.[27] Short-acting opioids such as fentanyl, alfentanil, and remifentanil decrease IOP on induction of anesthesia.[28,29] Midazolam has little effect on IOP,[30] and sedation with midazolam has been used to facilitate the measurement of IOP in children.[31] Nondepolarizing neuromuscular blocking agents (NMBAs) such as rocuronium, vecuronium, and atracurium have little effect on IOP. Succinylcholine increases IOP by about 8 to 10 mm Hg[32] due to a variety of postulated mechanisms including reduced aqueous humor outflow, increased choroidal blood volume, and increased central venous pressure.[33,34] IOP increases after reversal of nondepolarizing NMBA with neostigmine and atropine but remains unchanged with sugammadex.[35]

The most significant rise in IOP during general anesthesia occurs at laryngoscopy and emergence; the increase in IOP is even greater with repeat laryngoscopy.[36] Video-guided laryngoscopy causes a smaller increase in IOP than direct laryngoscopy.[37,38] Insertion of a laryngeal mask airway results in little or no increase in IOP.[39,40] Other anesthetic interventions that increase IOP include compression of the eyes by ventilation, hypoxia, hypercapnia, and hypertension.[34] Coughing, straining, or vomiting can increase IOP 30 to 40 mm Hg. A poorly placed anesthesia mask can put enough pressure on the eye to reduce blood flow to zero. Ocular blocks initially increase IOP by 5 to 10 mm Hg, but this falls to below baseline values within 5 minutes. Peribulbar blocks cause the greatest increase in IOP, likely due to the greater volume of local anesthetic that is injected.[41]

Physiological factors that increase IOP include being placed in supine, prone, or Trendelenburg positions. A normal blink increases the IOP by 10 mm Hg, while a forceful lid squeeze can increase IOP to more than 70 mm Hg.[42]

OPHTHALMIC DRUGS

Ophthalmic medications can be delivered by topical, ocular (intravitreal, subconjunctival, retrobulbar, and intracameral), and systemic methods. Topical eye drops may be absorbed systemically; significant routes of systemic absorption occur at conjunctival capillaries and nasal mucosa. Less significant absorption can occur through the lacrimal drainage system, pharynx, gastrointestinal tract, skin at the cheek and eyelids, and at the aqueous humor and inner ocular tissues.[43] When systemic therapy is required, the blood ocular barrier may inhibit passage of lipophilic drugs; however, this barrier may be impaired by ocular inflammation, intraocular surgery and trauma, or ocular diseases.[44] The population at risk of systemic side effects of eye drops are children and the elderly because of anatomical differences, risk of toxicity, the presence of concomitant diseases, and polypharmacy. Most drugs have negligible excretion into breastmilk, with the exception of Timolol eye drops, which can potentially cause adverse effects in the nursing infant.[45]

The total dose of a drug delivered by topical eye drop can be significant. Consider that one drop (typically 50 μL) of 10% phenylephrine contains 5 mg of drug, which is appreciably more than the intravenous dose of phenylephrine (0.05-0.1 mg). Adverse reactions such as hypertension, arrhythmias, and adverse cardiac events have been reported.[46]

Systemically administered drugs such as acetazolamide and mannitol can produce side effects such as fluid or electrolyte disturbance that can affect anesthetic management of these patients. Table 69.1 lists the systemic effects of ophthalmic medications.

OPHTHALMIC PROCEDURES

1. CATARACT EXTRACTION
   Cataracts are opacities of the crystalline lens of the eye. Cataract extraction is performed under topical or regional block. General anesthesia is rarely used.
   a. Phacoemulsification is the technique of choice for cataract surgery and refers to the use of ultrasonic vibration of fragments of the lens with simultaneous irrigation and aspiration. This technique allows for very small incisions. Femtosecond laser is a relatively new technique where laser energy is used for corneal incision, capsulotomy, and fragmenting the lens. Supplemental oxygen is contraindicated during its use because of fire risk.
   b. Extracapsular cataract extraction refers to the removal of the lens, while leaving the posterior lens capsule and zonules intact to allow implantation of intraocular lens.
   c. Intracapsular cataract extraction is the total removal of the opaque lens with the lens capsule, and it is rarely performed due to large incision and a relatively high rate of complications.
2 GLAUCOMA PROCEDURES
   d. Trabeculectomy is a glaucoma surgery that creates a transscleral fistula to allow aqueous humor to drain into the subconjunctival space. Mitomycin C or 5-flurouracil (5-FU) is usually used to prevent scarring of the flap.
   e. Baerveldt and Ahmed devices are drainage implantable devices that shunt aqueous humor under the conjunctiva.
   f. Minimally invasive glaucoma surgery (MIGS) includes procedures such as CyPass, iStents, and trabectome.
3. CORNEAL PROCEDURES
   a. Penetrating keratoplasty is a full thickness corneal transplant.

TABLE 69.1 Systemic Side Effects of Ophthalmic Drugs

Drug	Mechanism	Use	Side Effects
Acetylcholine	Cholinergic agonist	Meiosis	Bradycardia, bronchospasm, hypotension
Acetazolamide (PO, IV, IM)	Carbonic anhydrase inhibitor	Decrease IOP, Glaucoma	Confusion, drowsiness, hypokalemia, hyponatremia, metabolic acidosis, abnormal hepatic function tests, polyuria, renal failure
Anti-VEGF, e.g., ranibizumab, aflibercept	Inhibits vascular endothelial growth factor	Inhibits neovascularization	Conjunctival hemorrhage, eye pain, endophthalmitis, uveitis, stroke (in high-risk patients)
Atropine	Anticholinergic	Mydriasis	Dry mouth, dry skin, fever, agitation (central anticholinergic syndrome)
Cyclopentolate	Anticholinergic	Mydriasis, cycloplegia	Central anticholinergic syndrome (see atropine)
Echothiopate	Irreversible cholinesterase inhibitor	Glaucoma	Total body inhibition of plasma cholinesterase Prolongs effects of succinylcholine
Epinephrine	α-, β agonist	Mydriasis, decrease IOP	Hypertension, tachycardia, ventricular arrhythmias
Mannitol	Osmotic diuretic	Decrease IOP	Initial increase in circulating blood volume; congestive heart failure in patients with poor ventricular function
Phenylephrine	α Adrenergic agonist	Mydriasis, vasoconstriction	Hypertension
Pilocarpine	Cholinergic	Constrict pupil	Bradycardia, bronchospasm
Scopolamine	Anticholinergic	Mydriasis, cycloplegia	Central anticholinergic syndrome (see atropine)
Tamsulosin	α_1 antagonist	Benign prostatic hyperplasia	Floppy iris syndrome
Timolol	β_1 and β_2 antagonist	Glaucoma	Bradycardia, bronchospasm, exacerbate congestive heart failure

IM, Intramuscular; *IOP,* intraocular pressure; *IV,* intravenous; *PO,* per os, by mouth; *VEGF,* vascular endothelial growth factor.

b. Lamellar keratoplasty—In Descemet stripping endothelial keratoplasty (DSEK) and Descemet membrane endothelial keratoplasty (DMEK) procedures, only the diseased endothelium is removed and replaced with a corneal graft.

c. Pterygium excision—A pterygium is an abnormal growth of fleshy tissue on the conjunctiva. Excision is performed when it impinges on the cornea, affecting vision, or for cosmesis.

4. VITREORETINAL SURGERY

a. Vitrectomy is the surgical removal of the vitreous humor and its replacement with a physiologic solution. A posterior vitrectomy is indicated for the removal of foreign bodies such as “dropped lens” through the torn posterior capsule during cataract surgery, to repair retinal detachments, to remove membranes and media opacities, and to alleviate vitreous traction on the retina.

b. Scleral buckle is a procedure used for the treatment of retinal detachment. A silicone band is placed around the globe within the extraocular muscles under the conjunctiva to push the sclera toward the detached retina. It can be used as the sole treatment or in combination with vitrectomy to treat retinal detachment.

c. Radioactive plaque implantation is done for the treatment of choroidal melanoma. It is frequently combined with prophylactic vitrectomy with silicone oil injection to prevent retinal detachment from radiation.

5. OCULOPLASTIC SURGERY

a. Eyelid procedures. Eyelid procedures include the correction of ectropion (eyelid turning outward), entropion (eyelid turning inward), ptosis (drooping of the upper eyelid), and blepharoplasty (to remove redundant tissue of the eyelid).

b. Dacryocystorhinostomy refers to the surgical reopening of the obstructed channel between the lacrimal sac and the nasal cavity caused by a congenital defect or chronic infection.

c. Orbital surgery includes repair of blowout fractures, drainage of an orbital abscess, decompression for exophthalmos caused by hyperthyroidism, or tumor excision in the orbit or optic nerve.

d. Evisceration, enucleation, and exenteration. Evisceration refers to the removal of the contents of the eye. Enucleation refers to removal of the eye itself including the globe, but leaving orbital contents such as bone, extraocular muscles, and fat in place. Exenteration refers to the removal of the entire contents of the orbit including the lacrimal gland, optic nerve, and orbital bones.

e. Tarsorrhaphy is the partial or total suturing together of the eyelids.

Preoperative Evaluation

Exclusion criteria for ambulatory ophthalmic surgery under general anesthesia include noncompensated congenital cardiac and pulmonary disease, and some syndromes with multiple system involvement in pediatric patients. Severe cardiomyopathy, pulmonary hypertension, home-oxygen dependence, and super-morbid obesity (body mass index >50) are exclusion criteria in adult patients. Known difficult airway in either group may preclude outpatient surgery.

LABORATORY STUDIES

Previous investigations have shown that preoperative laboratory tests are typically normal before low-risk ambulatory surgery,[47,48] and the ASA recommends that routine preoperative laboratory testing before cataract surgery is not necessary in ASA physical status classification I and II patients.[49] Routine preoperative testing has not been shown to decrease cancellation rate and adverse events, or to improve outcomes.[50] While this is not extensively studied in other types of ophthalmic surgical procedures, a study examining preoperative medical testing for patients undergoing vitreoretinal surgery showed that preoperative testing did not influence rates of postoperative systemic complications.[51] Any laboratory testing, including an electrocardiography, should be based on the patients' history and physical findings rather than the indiscriminate ordering of a battery of tests.

CARDIOVASCULAR EVALUATION

The American Heart Association and American College of Cardiology have published guidelines for perioperative cardiovascular evaluation for noncardiac surgery.[52] Ophthalmic procedures, such as cataract extraction, are specifically identified as low-risk procedures. For these procedures, evaluation is focused on patients with major clinical predictors of risk.

ANTICOAGULATION

Many elderly patients undergoing eye surgery are on antiplatelet or warfarin therapy. Perioperative management of anticoagulants involves weighing the risks of thrombosis versus hemorrhagic complications. In a study of more than 19,000 cataract procedures, the incidence of hemorrhagic and thrombotic complications was low.[53] The risk of hemorrhagic complications depends on the degree of anticoagulation and the hemorrhagic potential of the surgical procedure. Serious hemorrhagic complications are most probable in orbital and oculoplastic surgery; of intermediate probability in vitreoretinal, glaucoma, and corneal transplant surgery; and least likely in cataract surgery.

It is safe to proceed with cataract surgery without stopping antiplatelet or warfarin therapy provided that the international normalized ratio level is within the therapeutic range.[54] Ocular blocks are rarely associated with severe hemorrhagic complications. For intermediate risk surgery such as oculoplastic and glaucoma surgery, warfarin and antiplatelet drugs may increase the risk of intraoperative or postoperative bleeding.[55,56] MIGS are associated with a 100% rate of hyphema, and the effects of anticoagulation therapy in patients undergoing these procedures is unclear.[57]

There is limited data on the risk of hemorrhagic complications during eye surgery in patients who are taking novel oral anticoagulants (NOACs). A recent systematic review and meta-analysis found that NOACs reduced the risk of intraocular bleeding by onefifth compared with warfarin.[58] However, another study comparing NOACs with antithrombotic drugs found no difference in the risk of substantial intraocular bleed, but the number of adverse events was scarce.[59] In the authors' institution, the ophthalmologist requests patients to stop NOAC therapy 2 days before intermediate-risk surgery.

If an interruption of anticoagulation treatment is needed, an individualized approach is recommended to minimize the risk of perioperative bleeding. Bridging therapy should be considered in patients with a high risk for thromboembolic events.

Orbital Blocks

Intraocular surgery can be performed under local, regional, or general anesthesia. Regional anesthesia is standard for most ophthalmic procedures such as cataract, glaucoma, cornea, and vitreoretinal surgeries.[60] Regional anesthesia provides akinesia (immobility) and anesthesia of the eye. The requirement for akinesia will vary by type of surgery and surgeon preference. Facial nerve block may be required to obtain akinesia of the orbicularis oculi muscle of the lid, as its motor innervation is located outside the cone.

Regional anesthesia techniques are generally reliable, safe, and provide good postoperative analgesia. Compared with general anesthesia, regional anesthesia is less likely to be associated with PONV. Patients are often able to bypass Phase 1 recovery with a quicker discharge home. Patients often view eye blocks with anxiety and apprehension, and may have fears of being aware and awake during their procedure. Some patients may not be able to cooperate, to lay flat, or lie still during surgery, and therefore may not be able to tolerate surgery under regional anesthesia alone.

RETROBULBAR BLOCK

Retrobulbar block has long been considered the gold standard of regional techniques for ophthalmic surgery until the 1990s with the introduction of peribulbar block and sub-Tenon block. Retrobulbar block is achieved by injecting local anesthetic inside the muscular cone (Fig. 69.2).

With the globe in primary gaze, a 3-cm, 23- to 27-gauge needle with its bevel opening faced toward the globe is placed at the junction of the inferior and lateral walls of the orbit just above the inferior orbital rim.[61] The needle is advanced parallel to the orbit floor (with a 10-degree elevation from the transverse plane) for approximately 15 mm until it is past the equator of the eye. The needle is turned medially and slight upward to aim toward an imaginary point behind the globe on the axis formed by the pupil and the macula where 2 to 5 mL of local anesthetic solution is injected. The needle tip approaches but does not pass the midsagittal plane of the globe. Some intorsion on downgaze is expected because the superior oblique muscle is outside the muscle cone and may not be blocked. Many modifications to the classical retrobulbar anesthetic injection have been described to minimize complications of the block. Traditionally, blunt-tipped needles were advocated because they were thought to protect against ocular trauma and because they allowed more accurate definition of tissue planes. However, studies have shown that blunt needles are as likely as sharp needles to cause globe penetration and optic nerve injury. Fine cutting needles produce minimal tissue distortion with little pain.[62] Compared with peribulbar block, retrobulbar block has a quicker onset and is associated with less chemosis.

Retrobulbar hemorrhage complicates about 1% of retrobulbar injections.[63] Venous hemorrhage spreads slowly and does not usually result in long-term visual problems. Arterial hemorrhage can produce rapid orbital swelling, marked proptosis with immobility of the globe, inability to close the lids, and massive blood staining of the lids and conjunctiva. Compressive hematoma can threaten retinal perfusion leading to severe visual loss. Ophthalmoscopic examination should be performed to evaluate for ischemic damage to the optic nerve or retina. IOP should be measured and a lateral canthotomy may need to be performed to decompress the orbit.

Intravascular injection can occur despite a negative aspiration test. The total dose of local anesthetic used is small, and systemic effects are unlikely, even if the total dose is given intravenously. Accidental intraarterial injection can cause central nervous system excitation and seizures. This occurs because of retrograde passage of local anesthetic solution from the ophthalmic artery to the internal carotid artery and delivery to the thalamus and other midbrain structures. Injection of local anesthetic or retrograde tracking of local anesthetic along the optic nerve sheath into the subdural or subarachnoid space causes partial or total progressive brainstem anesthesia. Wide ranging symptoms occur, from aphasia, confusion, and dysphagia to apnea, cardiac arrest, loss of consciousness, and seizures.[64,65] Management is supportive and should result in total recovery within several hours.

Optic nerve damage, or globe perforation with retinal detachment and vitreous hemorrhage, are devastating complications of retrobulbar block. Risk factors include physician inexperience and a highly myopic eye (axial length longer than 25 mm). This complication is associated with a poor prognosis, particularly in cases of delayed diagnosis.[66]

PERIBULBAR BLOCK

Peribulbar block was first reported in 1986.[67] The needle is introduced outside the cone, thus preventing retrobulbar hemorrhage and reducing the risk of optic nerve injury (see Fig. 69.2). Many modifications of this block exist; the classic technique involves two injections—one inferiorly and temporally and the second superiorly and nasally. Peribulbar anesthesia may also be administered with one injection; a 3 cm, 23-gauge Atkinson needle is placed at the junction of the middle and lateral thirds of the lower lid just above the inferior orbital rim. The needle should be directed vertically backward, parallel to the floor of the orbit. The needle insertion depth should be less than 25 mm. If contact is made with bone, the needle should be redirected slightly upward then 5 to 10 mL of local anesthetic is injected.[68] Studies support the use of peribulbar block in providing equivalent patient analgesia and operating conditions as retrobulbar block for a variety of ophthalmic procedures.[69,70]

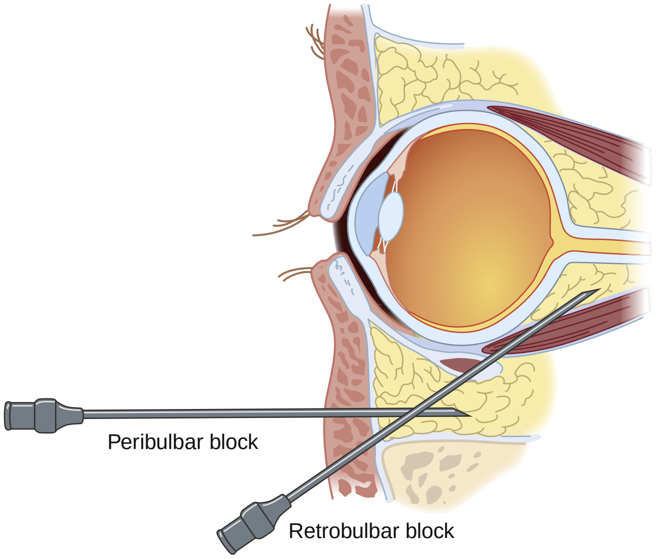

Fig. 69.2 Position of needles for retrobulbar and peribulbar blocks. (Redrawn from Spaeth GL. *Ophthalmic Surgery: Principles and Practice.* Philadelphia: WB Saunders; 1982.)

SUB-TENON BLOCK

To avoid the complications of sharp needles, a technique was developed using a blunt cannula under the fascia of Tenon.[71] Various lengths of cannulas have been used. Using topical anesthesia with sedation, a speculum is placed to retract the lids. A 2- to 3-mm spot of cautery can be made 5 mm from the limbus in the inferonasal or inferolateral quadrant. A 2-mm incision is made in the conjunctiva with blunt dissection through the fascia. A blunt cannula is directed posteriorly, but not beyond the equator of the globe, with injection of 1 to 3 mL of local anesthetic. A small degree of conjunctival edema is often seen. Analgesia is usually excellent.

FACIAL NERVE BLOCK

A facial nerve block is performed to prevent squeezing of the eyelids, which interferes with surgery and increases IOP. Akinesia of the orbicularis muscle, which is supplied by the facial nerve, can be achieved by blocking the nerve at its terminal branches (Van Lint block) or proximal trunk (O'Brien or Nadbath-Rehman block).

1. Van Lint block: the needle is placed 1 cm lateral to the orbital rim, and 2 to 4 mL of anesthetic is injected along the superolateral and inferolateral orbital rims. The modified Van Lint block is a common variant achieved by inserting the needle 1 cm more lateral than the original insertion point to avoid lid edema. The disadvantages of this block include patient discomfort, proximity to the eye, and postoperative ecchymoses(Figure 69.3A).

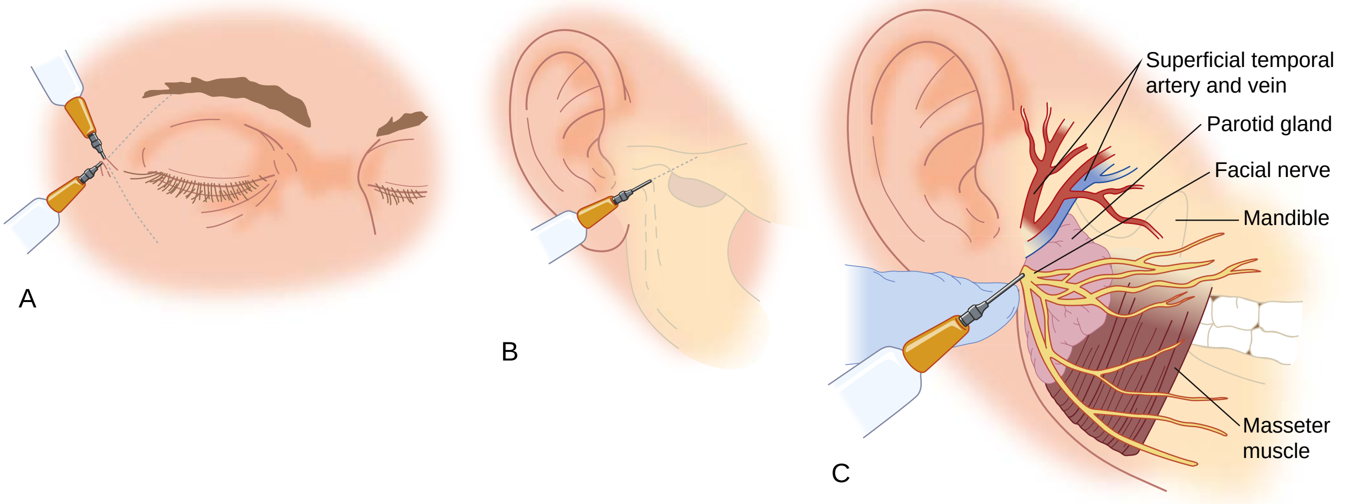

Fig. 69.3 Facial Nerve Blocks. (A) Van Lint; (B) O'Brien; (C) Nadbath-Rehman. (Redrawn from Spaeth GL. *Ophthalmic Surgery: Principles and Practice.* Philadelphia: WB Saunders; 1982.)

2. O'Brien block: the mandibular condyle is palpated inferior to the posterior zygomatic process and anterior to the tragus of the ear as the patient opens and closes the jaw. The needle is inserted perpendicular to the skin approximately 1 cm to the periosteum. As the needle is withdrawn, 3 mL of anesthetic is injected (Figure 69.3B).
3. Nadbath-Rehman block: a 12-mm, 25-gauge needle is inserted perpendicular to the skin between the mastoid process and the posterior border of the mandible. The needle is advanced its full length, and after careful aspiration, 3 mL of anesthetic is injected as the needle is withdrawn. This blocks the entire trunk of the facial nerve. The patient should be told to expect a lower facial droop for several hours postoperatively. The major disadvantage to this block is the proximity of the injection to important structures, such as the carotid artery and the glossopharyngeal nerve (Figure 69.3C).

LOCAL ANESTHETIC SOLUTIONS FOR REGIONAL TECHNIQUES

For local anesthesia, we use a 1:1 ratio of bupivacaine 0.75% and lidocaine 2% without epinephrine. Hyaluronidase is added to speed tissue penetration. Hyaluronidase can also be important in preventing anesthetic-related damage to the extraocular muscles. A human recombinant brand (Hylenex) is commercially available.

Monitored Anesthesia Care

Approximately 60% to 70% of ophthalmic procedures can be accomplished by a combination of orbital blocks and MAC. In the last 2 decades, the dramatic improvement in surgical techniques in ophthalmic surgery has had significant impact on anesthesia management rendering many ophthalmic procedures less invasive and shorter in duration.

MAC with regional anesthesia provides many advantages over general anesthesia in lowering postoperative morbidity, mortality, and pulmonary complications.[72,73] There is better postoperative pain control,[74] a lower incidence of intraoperative hypotension, faster postoperative recovery,[75] less PONV, and less unplanned hospital admission.[76]

Other than cataract surgery, most ophthalmic procedures require orbital blocks that are quick to perform but painful for the patient. Intravenous sedation and analgesia is provided to prevent pain and anxiety.[77] Patient movement during orbital blocks, either from pain, anxiety, under sedation, or over sedation, has been linked to complications leading to blindness. Other unique intraoperative conditions make ophthalmic surgery challenging. Many elderly patients are anxious[20] and cognitively impaired,[78] making it difficult for them to lie flat and still during surgery. Covering the face with surgical drapes and rotation of the bed 90 or 180 degrees away from the anesthesia provider also increases difficulty by limiting access to the airway.

The technique for MAC is highly variable and depends on the training and experience of the anesthesia provider, the environment of practice, availability of drugs, and the surgeons' and patients' expectation for sedation. There is no universal regimen for MAC.[79]

Intravenous sedation is a continuum ranging from mild and moderate sedation to deep sedation that overlaps with general anesthesia.[80] The depth of sedation can quickly increase to a deeper level depending on age, weight, cardiac function, genetics, and general health. Some patients have a high tolerance to sedatives while others may be more sensitive. This variability presents a challenge for the fast-track practice of ophthalmic anesthesia. The newly published "Practice Guidelines for Moderate Procedural Sedation and Analgesia 2018"[81] provides evidence-based recommendations for MAC that are also applicable in ophthalmic anesthesia.

TABLE 69.2 Observer's Assessment of Alertness/Sedation Scale

Subscore	Responsiveness	Speech	Facial Expression	Eyes
5	Responds to name spoken in normal tone	Normal	Normal	Clear
4	Lethargic response to name spoken in normal tone	Mild slowing or thickening	Mild relaxation	Glazed mild ptosis
3	Responds only after name spoken loudly or repeatedly	Slurring or slowing	Marked relaxation	Glazed marked ptosis
2	Responds after mild prodding or shaking	Few recognized words		
1	Does not respond to mild prodding or shaking			

From Chernik DA, Gillings D, Laine H, et al. Validity and reliability of the Observer's Assessment of Alertness/Sedation Scale: study with intravenous midazolam. *J Clin Psychopharmacol*. 1990;10(4):244–251.

The challenge of MAC in ophthalmic surgery is to quickly and safely sedate a patient adequately for an ocular block, and still maintain operating room efficiency. Ideally, the metrics of intravenous sedation in ophthalmic surgery should be quantitatively measurable, including the time required to reach the targeted level of sedation and analgesia, and the efficacy of pain control while avoiding respiratory depression or apnea. It is not necessary to use loss of consciousness as an endpoint of sedation. To do so can lead to apnea, hypoxia, involuntary movement in reaction to pain, and hemodynamic instability. During orbital blocks and surgery, patients should be sedated to a moderate level such as subscore 3 of the Observer's Assessment of Alertness/Sedation Scale (Table 69.2). The objective is to have a patient who is comfortable, free of pain and anxiety, yet able to follow commands in order to prevent movement that can lead to ocular trauma. Treating complications that occur during orbital blocks and being prepared to convert to general anesthesia in the event that MAC is inadequate, or the airway compromised are important responsibilities of the anesthesia provider.

MONITORED ANESTHESIA CARE FOR CATARACT SURGERY UNDER TOPICAL ANESTHESIA

Topical anesthesia has become popular due to its ease of administration and avoidance of complications of orbital blocks. Topical anesthesia requires patient cooperation because of the lack of ocular akinesia. Patients undergoing cataract surgery with topical anesthesia may experience some discomfort and require intravenous analgesic medication in small doses.[82] Most patients undergoing cataract surgery want sedation, which can be given either intravenously or orally.[83] Local anesthetic eye drops, such as 0.5% tetracaine, 0.75% bupivacaine, and 2% lidocaine, are very effective in producing analgesia although their effects can dissipate with constant irrigation.

With use of femtosecond laser, it may take up to 5 minutes to appropriately dock and position the patient, however it takes only 30 seconds for laser delivery. Discomfort during the procedure is managed with topical anesthesia. Ideally, sedation should be avoided to allow patient cooperation. If necessary, a small dose of a sedative or analgesic can be given.

Midazolam is the primary sedative used for anxiolysis during cataract surgery with topical anesthesia. Its side effects of over sedation, paradoxical reaction, postoperative neurocognitive disorders, and memory deficit are concerning in the elderly patient. Low-dose propofol, short-acting narcotics, or both are reasonable alternatives. Over sedation during cataract surgery should be avoided to prevent sudden awakening under surgery that may lead to undesired movement secondary to disorientation. Dexmedetomidine used as a sole medication is not appropriate for use in cataract surgery due to its slow onset, inadequate analgesic effect, and long elimination half-life.[83-85] Ketamine alone is also not a good choice due to its dysphoric and hallucinogenic properties. Intraoperative handholding is helpful to provide reassurance and reduce anxiety.

MONITORED ANESTHESIA CARE FOR OPHTHALMIC SURGERY WITH AN ORBITAL BLOCK

Orbital blocks, such as retrobulbar, peribulbar, and sub-Tenon blocks, are commonly performed nerve blocks for ophthalmic procedures. Orbital blocks are performed by either the ophthalmologist or the anesthesia provider. In an ASA Closed Claim Project analysis of complications associated with eye and peripheral nerve blocks, the risk of adverse events was increased when anesthesia providers performed both the orbital block and MAC.[10]

Many sedatives and analgesics, either alone or in combination, are used during the performance of an orbital block.[81] The use of sedatives alone such as midazolam, propofol, sodium thiopental, and dexmedetomidine can provide an adequate level of sedation, but their lack of analgesic effect may lead to involuntary head movement. The sole use of narcotics such as alfentanil, fentanyl, remifentanil, and sufentanil can provide profound analgesia, but inadequate sedation and increased nausea and vomiting.[86]

Propofol is an excellent drug for providing titratable sedation. Its lack of analgesic effect makes it insufficient for orbital blocks as evidenced by a high rate of involuntary movement during injection.[87] When ketamine is combined with propofol, up to onethird of patients who receive the combination will have undesired movement during the block.

The combination of a short-acting opioid such as alfentanil or fentanyl, and propofol, or a triple combination of propofol-midazolam-alfentanil produces a profound synergism of hypnosis and analgesia.[88,89] When opioids are administered in combination with midazolam,[90-92] propofol,[93] sodium thiopental,[94] ketamine,[95] and dexmedetomidine,[96] their sedative effects improved significantly.[91,93]

The use of a mixture of propofol, alfentanil (500 μg/mL), and lidocaine 1% in a 6:2:2 ratio in volume[97] is a novel approach in "balanced anesthesia" during MAC. It contains both a sedative and an analgesic in a single syringe that is easy to titrate based on the patient's age and weight (or adjusted weight in the obese). The addition of lidocaine attenuates the pain from propofol. Within 30 to 90 seconds, most patients reach an OAA/S subscore 3 sedation-level and are ready for the ocular block. This mixture provides excellent analgesia and sedation, as well as hemodynamic stability, with minimal need for airway support. While infusing the mixture bolus, assessing the patient's response to questions allows for detection of the target sedation level. Significant sedation may continue after the block for several minutes, however, conversing with and instructing the patient to breathe deeply will prevent hypoventilation and desaturation.

An orbital block provides analgesia for 2 to 3 hours, which will be sufficient for the duration of most ophthalmic procedures. For more complex procedures such as enucleation, dacryocystorhinostomy, orbital decompression, scleral buckle, and radioactive plaque implantation, the analgesic effect of a retrobulbar block may not be adequate to block all sensation. The addition of intravenous sedation with propofol and narcotics is sufficient for most patients. Low-dose ketamine and dexmedetomidine can be added to the sedation regimen in patients who continue to experience discomfort.

Intranasal dexmedetomidine is well absorbed without the profound bradycardia or hypotension associated with intravenous administration. When given as an adjunct agent, the dose should be reduced, 0.5 to 0.7 μg/kg, administered intranasally as a drop from a tuberculin (TB) syringe. The elimination half-life of dexmedetomidine is about 2 to 3 hours and even longer in elderly patients.[98] Giving a single bolus toward the beginning of the procedure allows the drug to be eliminated during surgery and prevents adverse effects in the PACU. Intranasal dexmedetomidine can also be used in highly anxious patients who are undergoing complex procedures under MAC.

The following are key points of anesthetic management for ophthalmic procedures under MAC.

1. Cataract surgery can be performed under topical anesthesia or an orbital block. Most patients require mild sedation (anxiolysis) for surgery performed under topical anesthesia. Moderate sedation is required for the performance of an orbital block, after which, mild sedation is adequate.
2. Dacryocystorhinostomy: the success of the anesthetic management depends on an adequate initial dose of narcotics and propofol to prevent pain associated with the injection of local anesthetics near the tear duct and inside the nose. A continuous infusion of low-dose propofol and intermittent doses of narcotics, such as fentanyl, are usually necessary to provide adequate analgesia. The patient must be awake enough to protect their airway from aspiration of blood that enters the oropharynx from the nasolacrimal system. Adding intravenous low-dose ketamine or intranasal dexmedetomidine can provide additional analgesia if necessary. If the procedure is bilateral or a reoperation, general anesthesia is likely a better choice.
3. Orbitotomy: the procedure can be done under MAC if performed primarily for debulking of soft tissue without bony involvement.
4. Radioactive plaque implantation: the procedure requires incision of the scleral layer and suturing the plaque between the extraocular muscles. Significant manipulation during the procedure can cause discomfort. Even a well-executed retrobulbar block may not provide complete analgesia; a moderate to deep level of sedation is usually required. Many institutions perform this surgery under general anesthesia, but at the authors' institution, MAC is routinely used. Continuous analgesia with narcotics, and a moderately dosed propofol infusion is highly effective. Low-dose ketamine or dexmedetomidine may be added for those patients who require additional analgesia.
5. Cornea transplant: partial-thickness corneal transplant and penetrating keratoplasty can be carried out under retrobulbar block. Some surgeons also perform a facial nerve block to prevent eyelid squeezing. Intraoperatively, sedation with continuous infusion of propofol and titration of narcotics to achieve a moderate level of sedation is the goal. The patient must be awake enough that they will not move inadvertently especially during penetrating keratoplasty.
6. Enucleation: this procedure can be performed with MAC in appropriate patients. In addition to a retrobulbar block, infiltration of the orbital area with bupivacaine at the end of the procedure can be helpful for postoperative analgesia. The anesthetic management is similar to that of radioactive plaque implantation discussed earlier.
7. Ruptured globe: ruptured globe injury can be repaired under an orbital block and MAC depending on the degree of injury.[99] It is crucial to minimize elevation of IOP during the block and surgery.

SPECIAL CONSIDERATIONS IN MONITORED ANESTHESIA CARE

1. Morbid obesity/obstructive sleep apnea (OSA). Morbid obesity has been identified as an independent predictor of sedation-related cardiopulmonary complications.[100] In addition to obesity-associated comorbidities, such as OSA, restrictive lung disease, diabetes mellitus, and coronary artery disease, obese patients are at increased risk of airway closure and hypoxia during sedation.[101] The pharmacokinetics of drugs are altered in the morbidly obese. Many drugs, including narcotics, should be dosed based on ideal body weight (IBW). When both propofol and alfentanil were given based on adjusted body weight, IBW + 30% of the difference between the patient's total body weight—IBW, the sedation level, analgesic effect, and incidence of airway events were comparable to normal weight patients.[97] Administration of 100% oxygen for several minutes, in addition to supplemental oxygen via nasal cannula before sedation, may alleviate hypoxemia during the orbital block.
2. Elderly patients have increased sensitivity to all sedatives and narcotics,[79,102] as well as increased risk of complications associated with MAC.[11] In addition to a reduction in drug dose requirement, the onset of action will be slower compared with younger patients.[79,97]

General Anesthesia

General anesthesia is indicated in approximately 30% of ophthalmic procedures, primarily for pediatric patients and in adults undergoing complex or invasive procedures whose anesthetic requirement cannot be met by orbital blocks and MAC. Adults with cognitive impairment, hearing loss, language barriers, claustrophobia, or who have a contraindication for an orbital block may require general anesthesia. The special considerations for general anesthesia in ophthalmic surgery should focus on the prevention of intraoperative patient movement that can lead to complications, such as coughing and bucking which can dramatically increase IOP, and the risk of periorbital hemorrhage after procedures such as orbital decompression or enucleation. PONV can cause elevation of IOP, prolonged PACU stay, and unanticipated hospital admission.

Fluid shifts are generally minimal in ophthalmic procedures. Significant blood loss is uncommon except for procedures such as orbital decompression, enucleation and evisceration, and lacrimal duct procedures. The main contributors to hemodynamic instability during general anesthesia in these patients are the patient's underlying comorbidity, such as advanced age, diabetes mellitus, and hypertension. Fluid deficits caused by fasting, autonomic dysfunction due to vascular disease, diabetes mellitus, and Parkinson disease, exaggerate the anesthetic effects on the cardiovascular system.

The laryngeal mask airway (LMA) is widely used in both adult and pediatric patients undergoing ophthalmic procedures that do not require paralysis. Those procedures include strabismus repair, scleral buckle, orbitotomy, enucleation, glaucoma, and cataract surgery in adults. The advantages of the LMA over an endotracheal tube include less hemodynamic changes upon insertion, minimal effect on IOP,[103,104] and the lack of requirement for muscle relaxants or intubating equipment.[105] A disadvantage of the LMA in ophthalmic surgery is that if there is difficulty with ventilation after the surgery is underway, the airway is difficult to access because it is close to the surgical field and often the patient's head is turned 90 degrees away from the anesthesia provider. If it becomes necessary to adjust the LMA or perform endotracheal intubation, the sterility of the surgical field can become compromised during those maneuvers.

Endotracheal intubation is required for penetrating keratoplasty, deep anterior lamellar keratoplasty, combined corneal transplantation and vitrectomy, and some vitreoretinal procedures, in order to provide muscle relaxation. Prevention of patient movement is critical during penetrating keratoplasty. In addition to ensuring an adequate depth of anesthesia, profound muscle relaxation must be ensured by the use of a nerve stimulator where 0/4 twitches and minimal posttetanic count are present while the diseased cornea has been removed and the eye is completely open. Movement at this time could result in extrusion of ocular contents or choroidal hemorrhage. Profound relaxation is required until the donor cornea is secured with eight sutures, when ocular contents are no longer open to the atmosphere. Sudden movement during vitreoretinal procedures where there are instruments inside the eye can also lead to injury that must be prevented. Profound levels of muscle relaxation can be reversed with sugammadex.

Intraoperative hypotension in elderly patients must be treated aggressively. Multiple studies have shown intraoperative hypotension (variously defined as systolic blood pressure <90 mm Hg or mean arterial pressure <50-55 mm Hg, depending on the study) to be associated with acute kidney injury, myocardial injury, stroke and mortality.[106-111] Intraoperative hypotension should be managed with a continuous infusion of phenylephrine instead of repeated phenylephrine boluses to maintain hemodynamic stability. In this situation, decreasing anesthetic depth to correct hypotension could potentially result in patient movement if there is inadequate muscle relaxation.

The prevention of coughing and bucking during emergence is another important goal in ophthalmic surgery because they both dramatically increase IOP,[34] and the incidence of hemorrhage in both intraocular and extraocular surgery. If there is no contraindication, a "deep" endotracheal extubation can be performed in patients who are breathing adequately at a deep level of anesthesia.[112,113] A number of other strategies are also useful in preventing coughing, such as the use of an LMA where appropriate. Total intravenous anesthesia (TIVA) with propofol is superior to sevoflurane, especially in smokers,[114] but it can delay emergence and PACU discharge. Propofol and sevoflurane are additive pharmacodynamically.[88] A combination of 0.5 minimum alveolar concentration of sevoflurane and infusion of propofol at 50 to 100 μg/kg/min is a reasonable approach to prevent coughing and postoperative delirium without delaying PACU discharge. In intubated patients, topical intratracheal lidocaine works slightly better than intravenous lidocaine. However, in cases lasting greater than 2 hours, the benefits of intratracheal lidocaine diminish.[115,116] If a "deep" endotracheal extubation is contraindicated, the patient should be suctioned while at a deep level of anesthesia, intravenous lidocaine given, and extubation performed as soon as safely possible.

Prevention of IOP fluctuation, especially in an open eye, glaucoma, and retinal detachment, can potentially reduce the risk of further eye injury. Video-guided laryngoscopy can significantly decrease the rise of IOP compared with direct laryngoscopy, as well as attenuate hemodynamic alterations.[37,117]

Prevention of PONV in ophthalmic surgery is important to improve patient satisfaction[118] and to prevent increases in IOP that are potentially harmful in relation to the procedure just performed. The treatment for the prevention of PONV should be determined by the Consensus Guidelines for the Management of PONV by Gan and colleagues.[119]

N_2O should be discontinued 15 to 20 minutes prior to the injection of sulphur hexafluoride (SF_6), or octafluoropropane (C_3F_8) used for retinal tamponade. N_2O is avoided for 3 weeks after injection of SF_6, or 8 weeks after C_3F_8 as it may increase the size of the gas bubble through diffusion. Patients are also advised to avoid air travel or high altitude because the reduced atmospheric pressure will lead to expansion of the intraocular gas bubble. Silicone oil is used for retinal tamponade in patients who need longer duration of tamponade, have difficulty in positioning, or cannot avoid air travel after surgery. Unlike gases, silicone oil is permanent and remains in the eye until surgically removed.[120]

Anesthesia for Pediatric Ophthalmology

Anesthesia for pediatric ophthalmology encompasses a diverse group of patients and procedures. Patients range from the premature infant with all the attendant comorbidities, to children with congenital syndromes, to healthy children and adolescents. Many ophthalmic procedures that are performed in adults under MAC require general anesthesia for a pediatric patient.

GLAUCOMA

Measurement of IOP and a thorough ocular examination in the awake child is often difficult due to lack of cooperation and therefore frequently requires general anesthesia. Anesthetic drugs and interventions, such as laryngoscopy, affect IOP. While accurate IOP measurement is important to the diagnosis and treatment of pediatric glaucoma, it is one of numerous diagnostic criteria. Examination of the optic nerve, pachymetry to measure corneal thickness, and gonioscopy of the iridocorneal angle are all important components of the examination. Trends in measurement of the IOP in the same patient over time, under the same conditions, are also useful in management.

An inhalation induction with sevoflurane is commonly performed in pediatric patients and is associated with a reduction in IOP within minutes. Premedication with oral midazolam facilitates a smooth induction, as agitation and crying will falsely elevate IOP. Oral midazolam appears to have no significant effect on IOP.[31] Oberacher and colleagues [31] studied the effect of oral midazolam in a group of young children and found no significant difference between the IOPs measured when awake versus sedated. Ketamine, which is thought to have minimal impact on IOP, has been used for sedation and IOP measurement in children. However, agitation and hallucinations during recovery have led to limited usefulness.

The ophthalmologist in coordination with the anesthesiologist is able to measure the IOP before a deep level of anesthesia is achieved. The ophthalmologist should be in the room with instruments ready prior to induction. The inhalational mask is positioned so that the ophthalmologist has unobstructed access to the eye. If necessary, the mask can be removed briefly to allow IOP measurement and then replaced. Unlike adults with glaucoma who are most often managed medically, pediatric patients are primarily treated with surgical interventions such as goniotomy, trabeculectomy, and pressure lowering devices.

About 10% of primary congenital glaucoma is inherited. Secondary glaucoma can be the result of a systemic condition such as neurofibromatosis, rubella, or Sturge-Weber syndrome (congenital capillary hemangiomatosis). However, most cases of pediatric glaucoma have no identifiable cause. These children require frequent examinations under anesthesia to monitor therapy. It is essential to establish a good rapport with the patient and family and to consider the use of premedication with midazolam and/or parental presence in order to achieve a smooth induction of anesthesia. An LMA is suitable for examinations under anesthesia, except for the very young infant where endotracheal intubation is preferred. If a surgical intervention is required, the LMA may be changed to an endotracheal tube at the discretion of the anesthesia provider.

STRABISMUS

Strabismus surgery is the most common type of ophthalmic surgery performed in children. It has historically been associated with an incidence of postoperative vomiting (POV) of more than 50% in numerous studies. Eberhart et al. identified strabismus surgery as an independent predictor for POV in children.[121] Additional independent predictors include age over 3 years, duration of surgery greater than 30 minutes, and a history of POV or PONV in the patient, sibling, or parent. When 2, 3, or 4 risk factors are present, the risk of POV is 30%, 55%, and 70%, respectively. With the development of risk scores and the Consensus Guidelines by Gan and colleagues[119] to predict and manage POV in children and PONV in adults, the incidence of these events has been dramatically reduced.

For children at high risk for POV (more than 2 risk factors), as those having strabismus surgery are, a combination of a 5-HT3 antagonist and a steroid should be administered prophylactically. Dexamethasone in a dose of 0.1 to 0.2 mg/kg at the beginning of the procedure, and ondansetron 0.1 mg/kg toward the end of the case is the recommended strategy. A propofol infusion at a subhypnotic dose in combination with other classes of antiemetics also reduces the incidence of POV.[122] Those children with all four risk factors should avoid receiving N_2O and inhalational anesthetics. TIVA with propofol should be considered in such cases. Droperidol is an effective antiemetic; however, the FDA "black box" warning has resulted in a dramatic decrease in its use.

The oculocardiac reflex is frequently elicited during strabismus repair by traction on the extraocular muscles (see the Oculocardiac Reflex section). When the response is profound, removal of the stimulus by the surgeon is the first step in resolution. The reflex usually accommodates over time and is rarely hemodynamically significant in healthy children. If, however, the bradycardia persists, it may be treated with an anticholinergic agent, either atropine or glycopyrrolate. A lesser known reflex, the oculorespiratory reflex leads to bradypnea and respiratory pauses.[123] The afferent limb is the same as for the oculocardiac reflex, the efferent limb has not been clearly established. It is not responsive to anticholinergics. The oculorespiratory reflex may be less appreciated because of the use of assisted modes of ventilation commonly used during strabismus surgery. Airway management is typically with an LMA unless a contraindication is present.

RETINOPATHY OF PREMATURITY

Retinopathy of prematurity (ROP) is a major cause of blindness and other visual disabilities in children throughout the world. Improved survival of extremely premature babies has led to an increased incidence. ROP was first linked with liberal oxygen use in premature infants in the 1940s. Setting target ranges of oxygen saturation in the 91% to 95% range has decreased the impact of oxygen as a risk factor.[124] Gestational age and low birth weight are major risk factors for the development of ROP. Other factors such as anemia, sepsis, and bronchopulmonary dysplasia (BPD) are also important predictors. Screening guidelines for ROP include a dilated fundus examination for all premature infants less than 30 weeks gestational age or 1500 grams at birth. Most of these initial screening exams are done in the neonatal intensive care unit without intervention from an anesthesia provider. Older infants may need to come to the operating room for surgery or laser treatments.

Care of the ex-premature infant is complex and starts with a thorough history with attention to gestational age, birth weight, neonatal intensive care unit (NICU) course, duration of intubation and ventilation, history of apnea and bradycardia, the presence BPD, and any congenital anomalies. Abnormalities of pulmonary function are common in children with BPD and many have increased airway reactivity.[125] This is an important consideration when any formerly premature child who has had BPD undergoes a surgical procedure. As with ROP, younger infants are surviving with BPD and the long-term sequelae are not completely known.

Although it has been more than 30 years since the initial recommendation for monitoring the formerly preterm infant following general or regional anesthesia, those recommendations are still current.[126] There is interinstitutional variation with the most conservative centers recommending monitoring for apnea and bradycardia for at least 12 hours until 60 weeks postconceptual age (PCA). Some infants who have had a complicated NICU course and continue to be oxygen dependent at home, have anemia, or continue to have episodes of apnea and bradycardia would not be suitable candidates to have surgery performed in an outpatient setting despite being greater than 60 weeks PCA.

General anesthesia is required for infants and children having laser treatments and other surgical interventions for ROP. The need for a motionless field is best ensured by endotracheal intubation and the use of muscle relaxants. Some infants may have been recently extubated, and it may be difficult to extubate at the end of the surgical procedure. They may experience periodic breathing upon emergence from anesthesia, in which case, the patient should be returned to the NICU and extubated when fully recovered.

Postoperative Considerations in Ophthalmic Surgery

It is commonly assumed that ophthalmic surgery is associated with little postoperative pain. While this may be true of cataract surgery,[127] significant postoperative pain is associated with posterior segment surgery, corneal surgery, ocular muscle surgery, and enucleations.[128] Yet, pain in ophthalmic surgery is often underrecognized, and postoperative pain management in complex ophthalmic surgery is frequently inadequate.[129] Postoperative pain after ophthalmic surgery is preferably treated with multimodal analgesia such as acetaminophen (oral or intravenous), nonsteroidal antiinflammatory medications, gabapentin, and regional block. Opioid use should be limited, as opioid prescription after short-stay surgery is a risk factor for chronic opioid use 1 year after discharge.[130]

Postoperative pain after cataract surgery is usually associated with ocular dryness, stinging, burning associated with topical medications, photophobia, or corneal abrasion as a result of the eyelid speculum being inserted or removed or corneal surface desiccation during surgery. Pain after cataract surgery is usually short-lived. Persistent pain may indicate complications such as choroidal effusion, suprachoroidal hemorrhage, and aqueous misdirection syndrome.[131] In the PACU, it is additionally important to consider elevated IOP as a potential cause of postoperative pain and PONV. Vasovagal syncope may also occur in the PACU especially in patients who have undergone strabismus surgery, and in those who have preexisting autonomic dysfunction. It is also seen in patients who sit up too quickly after being in a head-down position for an hour or two following insertion of a gas bubble during vitreoretinal surgery. Treatment is supportive and should include administration of oxygen, intravenous fluids, and anticholinergic drugs. The patient should be positioned supine with the head lower than the level of the heart.

Visual impairment is associated with an increased risk of falls, which is a leading cause of death and significant morbidity in the elderly.[132] Special care must be extended to minimize the risk of falls in elderly patients who have undergone ophthalmic surgery and have a patched eye; this is even more important in those with poor vision in the nonsurgical eye.

Ophthalmic Emergencies

Most urgent ophthalmic procedures do not need to be performed on an emergent basis. This is important because the anesthetic plan must consider the fasting status and general medical condition of the patient. In true eye emergencies, therapy should be started within minutes to hours of their recognition.

True emergencies such as ocular burns and central retinal artery occlusion require immediate intervention to prevent loss of sight. **Urgent situations** include open-globe injuries, endophthalmitis, acute narrow-angle glaucoma, acute retinal detachment, corneal foreign body, and lid laceration. Semiurgent conditions include ocular tumors, blowout fractures of the orbit, congenital cataract, and chronic retinal detachment. Treatment for these conditions should be started within days, but in some cases can be safely scheduled within weeks if necessary.

OPEN GLOBE AND FULL STOMACH

In a patient with a penetrating eye injury who requires emergent or urgent surgery, the anesthesia provider must protect the patient from pulmonary aspiration of stomach contents while protecting the eye from acute changes in IOP. Succinylcholine, used as part of a rapid-sequence induction of anesthesia to permit rapid intubation and airway protection, causes a modest increase in IOP of 8 to 10 mm Hg. There has been longstanding controversy surrounding the use of succinylcholine based primarily on anecdotal reports of vitreous loss during open eye surgery.[133] There have been a number of studies where no extrusion of ocular contents has occurred following succinylcholine use.[134-136]

There are also no claims for such injury since 2000 in the ASA Closed Claims Project that is designed to detect patterns of injury during anesthesia.[137] It should be stressed that during induction of anesthesia, there are many factors that may increase IOP such as crying, coughing, bucking, or straining particularly during suboptimal intubating conditions. All of these events increase IOP significantly more than succinylcholine. Based on the current evidence, succinylcholine may be used to facilitate endotracheal intubation in open eye injuries, despite its effect on IOP.

An alternative option for those at risk for aspiration is to use higher dose rocuronium (0.9-1.2 mg/kg) and to reverse neuromuscular blockade with sugammadex. Attempts to perform laryngoscopy and intubation before onset of complete neuromuscular blockade may result in straining or coughing that will dramatically increase IOP; therefore a peripheral nerve stimulator should be used to ensure adequate relaxation. This technique leaves the patient at risk for aspiration of gastric contents for a longer period of time (90-120 seconds) than if succinylcholine is used. A smooth emergence from anesthesia can be achieved by the well-timed use of narcotics to prevent strenuous coughing and bucking prior to extubation.

Additional factors implicated in increasing IOP are mask pressure, hypercarbia, hypoxia, and elevated arterial blood pressure. Regional anesthetic techniques with intravenous sedation can also be used in selected cases of open-globe injuries.[138]

Anesthesia-Related Eye Injuries

Eye injuries that occur during anesthesia for nonocular surgery are uncommon. Corneal abrasion is the most common eye injury,[9] and may be due to direct contact from the face mask, surgical drapes, or other foreign objects that come in contact with the eye. General anesthesia predisposes to corneal abrasion because it suppresses corneal reflexes, increases lagophthalmos (incomplete eyelid closure), and decreases tear production and stability.[139] Patients complain of a foreign body sensation—pain that is made worse by blinking, tearing, and photophobia. In some instances, the pain from corneal abrasion is far worse than the pain from the surgical site. Corneal abrasion can be prevented by lubricating the eyes with ophthalmic ointment, taping the eyes during surgery, and vigilantly monitoring patients to ensure that they do not rub their face or eyes during emergence from anesthesia. Treatment of corneal abrasion consists of antibiotic ointment to the affected eye and patching the eye for 48 to 72 hours.

Risk factors for postoperative ophthalmic complications include cardiopulmonary surgery, intraoperative hypotension, massive blood loss, anemia, and patients placed in prone or steep Trendelenburg positions. IOP can increase by an average of 13 mm Hg higher than preanesthesia induction values when a patient is placed in steep Trendelenburg position,[140] and remains significantly elevated while the patient remains in this position.[141] Mechanisms for increased IOP in the Trendelenburg position include (1) raised central venous pressure due to gravitational forces that leads to increased orbital venous pressure and IOP, and (2) pneumoperitoneum causing increased choroidal blood volume which, in turn, increases IOP.[141] Dexmedetomidine has been shown to be effective in lowering IOP[142] and its use has been shown to attenuate the increase in IOP during laparoscopic surgery in steep Trendelenburg position without decreasing ocular perfusion pressure.[143]

A devastating but rare complication of surgery is perioperative visual loss (POVL), which is most often associated with cardiac, spine, and head and neck operations. Causes of POVL are ischemic optic neuropathy (ION), central retinal artery occlusion (CRAO), and cortical vision loss. The pathology of POVL varies with its underlying etiology; ION affects the optic nerve, CRAO occurs at the optic disc in the retina, and cortical blindness results from ischemic or embolic damage to the visual cortex or the optic radiations. Patients usually experience painless visual loss or decreased acuity, an afferent pupillary defect, and no light perception. Prognosis for recovery of vision is poor.

ION is the most commonly reported condition associated with POVL. It can be further subdivided into anterior ischemic optic neuropathy (AION) and posterior ischemic neuropathy (PION). AION is associated with damage to the optic nerve head and is more commonly seen after cardiac surgery. Damage to the rest of the optic nerve results in PION, and it is more commonly reported after spinal surgery.[144] In the ASA POVL Registry, ION was associated with estimated blood loss of greater than 1000 mL and anesthetic duration of more than 6 hours.[145] Although the etiology of perioperative ION is unknown, a possible hypothesis is that prone surgery leads to increased venous pressure and interstitial tissue edema that compromises blood flow to the optic nerve. Prevention involves careful preoperative counseling and screening, considering surgical options that reduce the risk of stroke, and staging long spinal surgeries in high-risk patients. Patient positioning should avoid direct ocular pressure, with the head positioned so that it is higher than the heart to reduce orbital edema. Hypotension and severe anemia should be avoided.[146]

In CRAO, interruption of the arterial supply to the retina most commonly occurs from increased IOP due to external pressure during positioning. Other causes include retrobulbar hemorrhage, occlusive disease of the retinal vasculature, and central retinal vein thrombosis.[146] Therapeutic interventions include lowering IOP with acetazolamide or osmotic diuretic agents,[147] induced hypercarbia, topical hypothermia, locally applied thrombolytic agents, and hyperbaric oxygen therapy.[148]

In an ASA closed claims analysis of eye injuries during ophthalmic surgery associated with anesthesia in 1992, Gild et al. found that patient movement such as bucking or coughing was the most common single mechanism of injury. The majority of patient movement occurred during general anesthesia, and the outcome in all these cases was blindness.[9] The use of a peripheral nerve stimulator to monitor neuromuscular blockade during ophthalmic surgery should ensure that patients do not move during general anesthesia.

Acute glaucoma, manifested as dull periorbital pain, during the early postoperative period may occur due to the administration of mydriatic agents such as atropine, scopolamine, and ephedrine. Management consists of lowering IOP with acetazolamide or an osmotic diuretic and timely referral to an ophthalmologist.[149]

Anesthesia for Otolaryngologic and Head-Neck Surgery

ANIL PATEL

KEY POINTS

- Difficult airways are more frequently encountered in patients undergoing ear, nose, and throat (ENT) surgery, especially for cancer. Reviewing the results of a preoperative computed tomography (CT) scan or an endoscopic airway examination may help identify pathologic features likely to produce airflow obstruction or complicate tracheal intubation.
- Although the tracheas of ENT patients are often intubated using ordinary polyvinyl chloride endotracheal tubes (ETTs), microlaryngeal, laser-safe, and wire-reinforced tubes are frequently employed.
- Endotracheal intubation in an awake patient with a flexible bronchoscope is commonly used when intubation following the induction of general anesthesia would be imprudent.
- Fiberoptic endotracheal intubation is usually well tolerated, is gentle on the airway, and does not require force to obtain glottic exposure.
- When the airway disorder is so extensive that awake endotracheal intubation is impractical, tracheostomy performed using local anesthesia (with or without judicious intravenous sedation) is usually the best option. In extreme loss-of-airway emergencies, a cricothyrotomy may be preferable to a tracheostomy because cricothyrotomy takes much less time to complete.
- In some head and neck cases, such as in patients undergoing parotid surgery, the need for electrical testing of the facial nerve precludes the extended use of neuromuscular blocking drugs.
- In many patients with head and neck disorders, gentle emergence from anesthesia, free of coughing and straining, is vitally important to prevent emergence rebleeding as a result of venous engorgement.
- Bleeding following tonsillectomy usually occurs within the first 6 postoperative hours, but it can also occur several days later.
- Facial trauma can produce unremitting bleeding and the aspiration of teeth, blood, bone, and tissue fragments, as well as cervical spine injury. Airway trauma can result from blunt or penetrating injuries, burns, inhalational injury, and iatrogenic causes. In both situations, initial management is dictated by the degree of respiratory distress or potential airway compromise, the available equipment, and clinical preferences.
- Intubating the trachea of a patient with laryngeal trauma may result in further injury to the airway or even complete airway loss. If intubation is attempted, it is advised to use a fiberoptic bronchoscope with a small ETT. Positive-pressure ventilation may worsen any subcutaneous emphysema. In some cases, a tracheostomy may be the most prudent course.
- Causes of stridor include inhaled foreign bodies, bilateral vocal cord palsy, airway edema, angioedema, epiglottitis, traumatic injury, subglottic stenosis, and other pathologic entities. Regardless, the first issue in the setting of stridor is whether or not endotracheal intubation or a surgical approach to the airway is immediately necessary to rescue the patient from death or injury. Heliox administered with a nonrebreathing facemask or high-flow nasal oxygen can be helpful as a temporizing measure.
- The chosen anesthetic technique for endoscopic procedures varies with patient and lesion particulars, clinical preferences, and the selected surgical tools (laser, rigid bronchoscope). Total intravenous anesthesia is a popular choice for many of these cases.
- Lasers can be used to vaporize otolaryngologic lesions; however, special precautions are needed to prevent accidental thermal injury or an airway fire, a potentially deadly complication that may also occur during tracheotomy surgery. Oxygen must be kept to a minimum when a significant potential for an airway fire exists. Moreover, nitrous oxide should not be used during airway surgery because it supports combustion just as does oxygen.

On October 16, 1846, Dr. William Morton famously used ether delivered by inhalation to provide general anesthesia to Gilbert Abbott and allow surgeon Dr. John Warren to remove a tumor from Abbott's neck.[1,2] From this first public demonstration of ether anesthesia onward, the relationship between anesthesiology and ear, nose, and throat (ENT) surgery has been vital. Indeed, no other branch of surgery has as great a need for a mutual understanding between the surgeon and the anesthesiologist, with joint procedural planning and close cooperation being crucial. For example, many ENT surgical procedures require that the anesthesia provider share the airway with the surgeon; consequently, a good anesthesia provider must be unusually knowledgeable about ENT procedures and the possible effects on the patient.

Anesthesia for ENT surgery encompasses a vast range of procedures varying enormously in complexity, duration, and potential for complications.[3] On any given day, ENT anesthesiologists may be assigned to simple high-volume cases, such as myringotomies and tonsillectomies, or to all-day procedures in patients with cancer. They may also encounter patients with severely distorted airway anatomy, sometimes even causing airway obstruction, as well as procedures involving tracheal, glottic, or subglottic surgery that require sharing of the airway in conjunction with the use of special equipment such as surgical lasers. Nasal procedures usually require airway protection from blood and secretions, as well as gentle emergence from anesthesia. Intraoral ENT procedures, such as tonsillectomies, may employ instruments intended to keep the mouth open but that may also unintentionally obstruct the airway. Extreme lateral rotation of the head may be required for some ear procedures. These are just some of the special perils of providing anesthesia for ENT procedures.

Synopsis of Ear, Nose, and Throat Anatomy

Figs. 70.1 to 70.4 illustrate various aspects of ENT anatomy. The oropharynx extends from the uvula to the hyoid bone. The hypopharynx extends from the hyoid to the cricoid cartilage. The glottis includes both vocal cords, the anterior commissure, and the posterior intraarytenoid area. The subglottis extends 5 mm (anteriorly) to 10 mm (posteriorly) below the apex of the vocal cords (also known as vocal folds). The larynx, essential to respiration and speech, has a clinically important glottic closure reflex mediated through bilateral superior laryngeal nerves. This reflex serves to protect the airway against aspiration. For example, swallowing activates this protective reflex. On occasion this protective reflex can be problematic because when sustained spasm of the glottic muscles (a condition known as laryngospasm) occurs,[4-6] gas exchange cannot take place. Laryngospasm is associated with light anesthesia and is frequently triggered by blood or secretions irritating the vocal cords, as often occurs after septoplasty and rhinoplasty surgery. Because it can make ventilation impossible, laryngospasm may constitute a true anesthetic emergency (see later).

Branches of the right and left vagus nerves innervate the larynx. The right vagus nerve gives rise to the right recurrent laryngeal nerve, whereas the left vagus nerve gives rise to the left recurrent laryngeal nerve. The two recurrent laryngeal nerves provide motor innervation to all the intrinsic muscles of the larynx, except the cricothyroid and inferior pharyngeal constrictor muscles, which are innervated by the branches of the superior laryngeal nerves. The internal laryngeal nerve is the internal branch of the superior laryngeal nerve (see Fig. 70.3). It descends to the thyrohyoid membrane, pierces it along with the superior laryngeal artery, and provides sensory innervation to the larynx down to the vocal cords. Sensory innervation below the vocal cords and to the upper trachea is supplied by the recurrent laryngeal nerves (see Fig. 70.3).

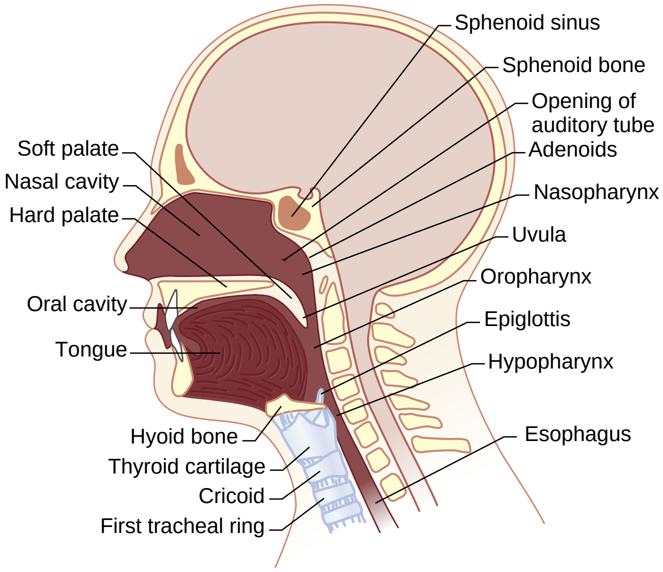

Fig. 70.1 Highlights of otolaryngologic anatomy. Note (1) the anterior position of the trachea relative to the esophagus; (2) the oropharynx, extending from the uvula to the hyoid bone; (3) the hypopharynx extending from the hyoid bone to the cricoid cartilage; (4) the cricoid ring, a structure that is pushed posteriorly during the Sellick maneuver component of rapid-sequence induction, done with the intention of occluding the esophagus to help prevent regurgitation of gastric contents; and (5) the location of the first tracheal ring, important as a surgical landmark because most tracheostomies are performed between the second and third tracheal rings. (From Feldman MA, Patel A. Anesthesia for eye, ear, nose, and throat surgery. In: Miller RD, ed. *Miller's Anesthesia*. 7th ed. Philadelphia: Churchill Livingstone; 2010:2357–2388.)

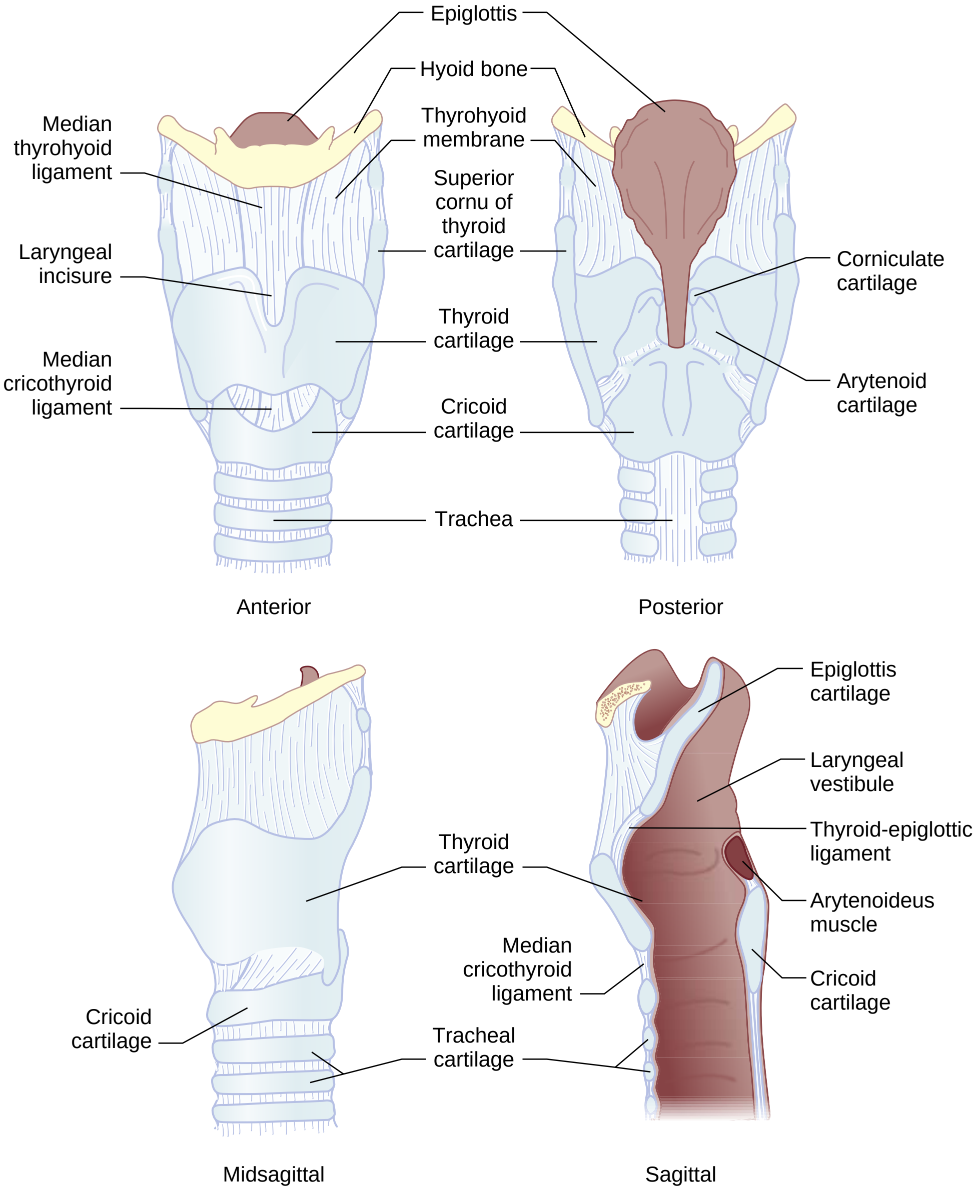
Injury to the recurrent laryngeal nerves, which supply most of the laryngeal intrinsic muscles, is a feared but often preventable complication in thyroid surgery and a host of other procedures, including tracheal intubation.[7-12] If the damage is unilateral, the patient may present with hoarseness from unilateral loss of vocal cord abduction occurring in conjunction with intact cricothyroid-mediated adduction. This situation causes the affected vocal cord to assume a paramedian position. Bilateral nerve damage can result in dyspnea, stridor, and even full airway obstruction from bilateral vocal cord paramedian positioning. Such patients may require a tracheostomy. Intraoperative neuromonitoring is often used to reduce the chance of injury to the recurrent laryngeal nerves, especially in thyroid surgery.[13-15]

Preoperative Evaluation for Ear, Nose, and Throat Surgery

Although the preoperative evaluation of the surgical patient is discussed in detail in Chapter 31, a few issues are especially pertinent to ENT cases. Many ENT patients, especially



Epiglottis
Hyoid bone
Median thyrohyoid ligament
Thyrohyoid membrane
Superior cornu of thyroid cartilage
Laryngeal incisure
Corniculate cartilage
Thyroid cartilage
Median cricothyroid ligament
Arytenoid cartilage
Cricoid cartilage
Trachea
Anterior
Posterior
Epiglottis cartilage
Laryngeal vestibule
Thyroid-epiglottic ligament
Thyroid cartilage
Arytenoideus muscle
Median cricothyroid ligament
Cricoid cartilage
Cricoid cartilage
Tracheal cartilage
Midsagittal
Sagittal

Fig. 70.2 Anterior, posterior, midsagittal, and sagittal views of laryngeal anatomy. Note (1) how the cartilaginous tracheal rings are incomplete posteriorly to allow the trachea to collapse slightly to facilitate the passage of food down the esophagus (and to provide orientation during bronchoscopic procedures!); (2) the superior cornu of the thyroid cartilage, an important landmark in the superior laryngeal nerve block because this is close to where the internal branch of the superior laryngeal nerve penetrates the thyrohyoid membrane; and (3) the median cricothyroid ligament and (not labeled) the twin lateral cricothyroid ligaments, known collectively as the cricothyroid ligament and entered in both emergency cricothyrotomy procedures and with emergency transtracheal jet ventilation. (From Feldman MA, Patel A. Anesthesia for eye, ear, nose, and throat surgery. In: Miller RD, ed. *Miller's Anesthesia*. 7th ed. Philadelphia: Churchill Livingstone; 2010:2357–2388.)

those with malignant head and neck diseases, have histories of prolonged tobacco and alcohol use, whereas many others suffer from obesity or obstructive sleep apnea (OSA). Patients with chronic airway obstruction may develop pulmonary hypertension, sometimes leading to right-sided heart failure (cor pulmonale). A history of hoarseness may signal recurrent laryngeal nerve injury or worse, whereas the presence of stridor is *always* a cause for immediate concern. In cases involving the airway, the anesthesiologist and surgeon frequently review available radiographic and video studies to establish an airway plan collaboratively. A history of head and neck radiation for malignancy treatment frequently makes intubation difficult because the structures may become tough and fibrotic ("like wood"), yet they are predisposed to bleeding with instrumentation. A history of snoring may signal that the patient has undiagnosed sleep apnea and is prone to airway obstruction.

ENT cases frequently involve geriatric patients, many of whom are at a high risk for postoperative delirium and cognitive dysfunction.[16-18] Although many ENT procedures involve infrequent risk, some of the large head and neck operation sare considered to have "intermediate" surgical risk. A preoperative resting 12-lead electrocardiogram (ECG) is recommended for patients with known coronary heart disease, peripheral arterial disease, or cerebrovascular disease who are undergoing such procedures. Additionally, patients with a history of heart failure, diabetes mellitus, or renal failure who are undergoing intermediate-risk operative procedures benefit from an ECG. Preoperative ECG testing is not indicated in asymptomatic persons undergoing infrequent-risk procedures.

Recurrent laryngeal nerve

Fig. 70.3 Laryngeal anatomy focusing primarily on the internal laryngeal nerve and the recurrent laryngeal nerve. The two recurrent laryngeal nerves provide motor innervation to all the intrinsic muscles of the larynx, except the cricothyroid and inferior pharyngeal constrictor muscles, which are innervated by the external branches of the two superior laryngeal nerves (external laryngeal nerve). Sensory innervation of the larynx down to the vocal cords is supplied by the internal laryngeal nerve branches of the superior laryngeal nerves (internal laryngeal nerve), these in turn being branches of the vagus. Sensory innervation below the vocal cords and to the upper trachea is supplied by the recurrent laryngeal nerves. (From Schuller DE, Schleuning AJ. *Otolaryngology: Head and Neck Surgery.* 8th ed. St. Louis: Mosby; 1994:252.)

A *preoperative endoscopic airway examination can be performed* in selected patients. This technique uses an ordinary flexible fiberscope usually used for awake endotracheal intubation to conduct a quick transnasal laryngoscopic examination using topical anesthesia. This examination allows the clinician to determine whether a problematic laryngeal disorder exists, such as supraglottic lesions that would not be apparent by ordinary means. The procedure requires minimal time and patient preparation, and it is well tolerated by patients. A review by Rosenblatt provides ample details.[19]

Airway Management in Otolaryngology

Both easy and difficult airways are frequently encountered in ENT anesthesia. The American Society of Anesthesiologists (ASA) Difficult Airway Algorithm (or similar algorithm),[20-28] should ordinarily be a starting point for nearly all aspects of ENT airway management. To a large extent, the specific airway management techniques chosen depend on clinical circumstances, the airway management skills and preferences of the anesthesiologist and surgeon, and the available equipment.

The following general management options exist: (1) general endotracheal anesthesia; (2) general anesthesia using a supraglottic airway (SGA) device (e.g., laryngeal mask airway [LMA]); (3) general anesthesia using an ENT laryngoscope (to expose the airway) in conjunction with jet ventilation; (4) use of intermittent apnea; (5) general anesthesia using the patient's natural airway, with or without adjuncts such as jaw positioning devices or nasopharyngeal airways; and (6) local anesthesia in conjunction with intravenous sedation, with the patient breathing spontaneously. The first option is doubtless the most popular. However, the technique chosen and implemented depends on factors such as the perceived difficulty of intubating the trachea with ordinary methods. Evaluation of the airway in this particular respect is also discussed in Chapter 44.

The airway can become obstructed for many reasons. Examples include the following: aspirated foreign bodies; infections such as epiglottitis, diphtheria, or Ludwig angina; laryngospasm; tumors and hematomas impinging on the airway; trauma to the airway; OSA; tonsillar hypertrophy; and airway edema (e.g., from anaphylaxis, prolonged laryngoscopy, or smoke inhalation or burn injury). In most cases, airway management is determined after a discussion between the anesthesia and surgical teams.

Most patients undergoing ENT surgery have their airway managed by tracheal intubation. Although under ordinary circumstances tracheal intubation is straightforward, patients whose tracheas are expected to be difficult to intubate can be identified and usually managed with techniques such as videolaryngoscopy or fiberoptic intubation. A key decision in such cases is whether the tracheal intubation should be performed with the patient awake or following the induction of general anesthesia. Another important decision is what tools or interventions to employ in the event that difficulty with ventilation or intubation is encountered. In exceptional cases, a tracheostomy using local anesthesia must be performed.

Patients for ENT surgery are often managed using an ordinary polyvinyl chloride (PVC) endotracheal tube (ETT), but microlaryngeal tubes (MLTs), laser tubes, and wire-reinforced tubes are also frequently used. Reinforced tubes

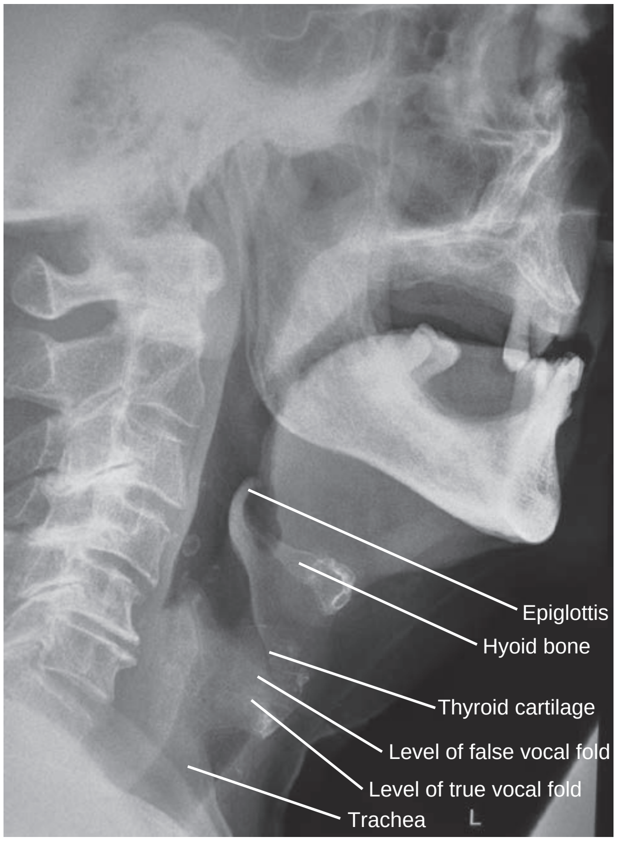

Fig. 70.4 Lateral radiograph demonstrating laryngeal anatomy. Notice (1) the normally wafer-thin epiglottis, which serves as a protective cover to the laryngeal inlet during swallowing and may become much larger and "thumb shaped" when edematous (e.g., as a result of pediatric epiglottitis); (2) the limited amount of prevertebral soft tissue in the oropharyngeal and hypopharyngeal regions; when edematous (e.g., as a result of a retropharyngeal abscess), this tissue may expand anteriorly to obstruct the airway; and (3) the hyoid bone, which aids in tongue movement and swallowing and which, if found fractured on autopsy, is suggestive of foul play by throttling or strangulation. (From Feldman MA, Patel A. Anesthesia for eye, ear, nose, and throat surgery. In Miller RD, ed. *Miller's Anesthesia*. 7th ed. Philadelphia: Churchill Livingstone; 2010:2357–2388.)

have the advantages that they are unlikely to kink and they fit especially well into tracheostomy stomas because of their excellent flexibility. Selection of laser-resistant ETTs should be made based on the material appropriate to the type of laser being used for the procedure. In addition, the tracheal cuff can be filled with saline dyed with methylene blue to allow immediate detection of laser injury to the cuff. Practical considerations in this setting start with the fact that the tube must be adequately secured using tape or other means; some maxillofacial surgeons suture the tube to the side of the mouth or even tie the tube to the teeth with wire. In addition, the ETT cuff pressures ordinarily must be kept less than 25 mm Hg to avoid ischemic damage to the tracheal mucosa. When nitrous oxide is used, cuff pressures gradually increase as nitrous oxide enters the cuff by diffusion. This is of particular concern in surgical procedures of long duration, such as free-flap surgery.

Before attempting tracheal intubation, its difficulty using direct laryngoscopy can often be predicted. The 11-point airway assessment tool included with the 2003 ASA Difficult Airway Algorithm is an excellent source of information and advice.[20] In addition, following the completion of tracheal intubation, the difficulty (if any) encountered should be summarized. The Intubation Difficulty Scale (IDS) introduced by Adnet and associates can be useful.[29-33] IDS is a numeric score indicating overall intubation difficulty based on seven descriptors associated with intubation difficulty: number of supplementary intubation attempts, number of supplementary operators, alternative techniques used, laryngoscopic grade, subjective lifting force, the use of external laryngeal manipulation, and the characteristics of the vocal cords.

Most endotracheal intubations are achieved using traditional Macintosh and Miller laryngoscopes, although several alternative laryngoscopes have been advocated. When the view at laryngoscopy is suboptimal, the use of introducers such as the Eschmann stylet (gum elastic bougie) can sometimes be very helpful.[34-39] It is used as follows: when a poor laryngoscopic view of the glottic structures is obtained, the introducer should be inserted into the patient's mouth and gently advanced through the glottic opening (in the case of a grade II view) or anteriorly under the epiglottis (in the case of a grade III view). Subtle clicks resulting from the introducer passing over the tracheal rings help confirm proper placement of the introducer. With the introducer held steady, one then "railroads" a tracheal tube over the introducer into the glottis.

Video laryngoscopes such as the GlideScope (Verathon, Bothell, WA), the McGrath (Covidien, Mansfield, MA) video laryngoscope, the Storz video laryngoscope (Karl Storz, Tuttlingen, Germany), and the Pentax AWS (Hoya Corporation, Tokyo) have become particularly valuable, especially in patients with an "anterior" larynx or in patients with cervical spine immobilization.[40-50]

As discussed in Chapter 44, awake endotracheal intubation involves ETT insertion in a conscious or lightly sedated patient. It is usually performed because endotracheal intubation during general anesthesia is judged to be too risky. Some concerns may reflect possible difficulties with ventilation or endotracheal intubation or possible aspiration of gastric contents. Although fiberoptic intubation using topical anesthesia is the most common approach to awake endotracheal intubation, other methods include awake blind nasal intubation using an Endotrol (or similar) ETT or the use of a Macintosh, Miller, GlideScope, or other laryngoscope with topical anesthesia. Certain airway blocks can be used in addition to topical anesthesia. These are discussed in Chapter 44.

The use of fiberoptic intubation for the airway management of patients undergoing otolaryngologic surgery is popular because this technique works well in the presence of many kinds of airway disease. Although fiberoptic intubation can often be safely performed during complete general anesthesia,[51] many clinicians opt to perform this technique using topical anesthesia with the patient only lightly sedated (awake fiberoptic intubation), depending on the skill level of the anesthesiologist, the cooperation of the patient, and the severity of the pathologic process. A central consideration behind the choice of "awake" versus "asleep" fiberoptic intubation is the safety margin an awake technique allows: if intubation is not successfully accomplished, the patient's ability to maintain his or her own airway remains intact. In addition, during awake intubation, airway reflexes are generally maintained sufficiently to guard against pulmonary aspiration, an important point in patients with a high risk of aspiration of gastric contents. Patients who have recently eaten and have undergone trauma are at especially high risk.

Awake endotracheal intubation is not synonymous with fiberoptic intubation. Awake intubation can be accomplished safely using many other airway devices. Other possible options for awake intubation include, but are not limited to, direct laryngoscopy with Macintosh and Miller laryngoscopes, blind nasal intubation, use of a GlideScope or other video laryngoscope, use of a lighted stylet, and so on.

Typically, in intubation of the trachea in an awake patient, the airway is initially anesthetized with gargled and atomized 4% lidocaine. Superior laryngeal and transtracheal blocks are occasionally also employed. In addition, judicious sedation is usually administered. Midazolam, fentanyl, remifentanil, ketamine, propofol, and clonidine have all been used in this setting. More recently, the use of dexmedetomidine, a selective α_2-agonist with sedative, analgesic, amnestic, and antisialagogue properties, has been reported. A key advantage of dexmedetomidine is that it maintains spontaneous respiration with minimal respiratory depression.[52-55] Patients being sedated with dexmedetomidine are generally easy to arouse. However, this advantage, along with that of maintaining spontaneous respiration, may not occur when very large doses are given.

Doyle described the successful use of the GlideScope in four cases of awake endotracheal intubation.[56] The potential advantages are as follows: first, the view is generally excellent. Second, the method is less affected by the presence of secretions or blood as compared with the use of fiberoptic intubation. Third, no special restrictions exist on the type of ETT that can be placed when using the GlideScope, but this is not the case for fiberoptic methods. Fourth, the GlideScope is much more rugged than a fiberoptic bronchoscope and is far less likely to be damaged with use. Advancing the ETT into the trachea over the fiberoptic bronchoscope often fails as a result of ETT impingement on the arytenoid cartilages; this is generally not a problem with the GlideScope.

In the end, however, the use of awake fiberoptic intubation in the setting of the patient with airway disease remains steadfastly popular because it is gentle to the airway, is generally well tolerated, and does not require the application of force to obtain glottic exposure.

Special mention needs to be made of the necessity of being fully prepared for dire ENT airway emergencies because these patients may require immediate surgical intervention. In addition to a conventional difficult airway cart, practitioners may wish to maintain a special ENT airway cart with equipment such as that listed in Box 70.1.[57] In addition to these items and unlisted items favored by individual practitioners, ENT surgeons want ready access to an emergency tracheotomy tray, as well as to some form of suspension laryngoscope or rigid bronchoscope. Special attention to the maintenance and cleaning of fiberoptic bronchoscopes is also important, given that they must always be easily accessible and reliable when needed. In the case of electronic fiberscopes incorporating a video display, it is particularly important to establish that illumination settings and white balancing have been correctly set before use.

BOX 70.1 **Possible Items for an Ear, Nose, and Throat Airway Emergencies Cart**

- Bag-valve-mask resuscitator (Ambu bag)
- Oropharyngeal and nasopharyngeal airways
- Supraglottic airway collection
- Endotracheal tubes, including microlaryngeal tubes and laser tubes
- Malleable stylets
- Topical anesthesia, with syringes, and atomizers
- Laryngoscope collection with extra bulbs and batteries
- Magill forceps (useful for nasal intubation)
- Boedeker forceps (for use with video laryngoscopes)*
- Airway introducer (gum elastic bougie)
- Tube exchange catheters
- Carbon dioxide detection system
- Video laryngoscope (e.g., GlideScope, McGrath, Pentax-AWS)
- Surgical airway kit (e.g., Melker cricothyrotomy kit)
- Emergency tracheotomy tray
- Fiberoptic bronchoscope

*The Boedeker (curved) intubation forceps is useful for removal of foreign bodies when a video laryngoscope is used.[57]

Airway Disorders in Otolaryngology

Otolaryngologic airway disorders can sometimes present the clinician with tremendous anesthetic and airway challenges. In many such cases, awake endotracheal intubation (e.g., by fiberoptic methods) is the method of choice. When awake intubation is impractical (e.g., overwhelming tumor invasion of the airway, inadequate equipment, limited experience), tracheostomy using local anesthesia (with minimal sedation, or no sedation in extreme cases) is sometimes preferred. In such cases, complete airway obstruction is the outcome most feared; this can occur when anesthetic drugs or neuromuscular blocking drugs decrease the tone of the airway musculature, thereby unfavorably changing the airway architecture.

Many ENT pathologic conditions can make airway management difficult. *Airway infections* can include upper airway abscesses, retropharyngeal abscesses, quinsy, Ludwig angina, and epiglottitis (supraglottitis). *Airway tumors* may be present as oral or tongue malignancies, as glottic, supraglottic, and infraglottic tumors, or as anterior mediastinal masses. *Other pathologic conditions* may also complicate airway management, such as congenital malformations (Pierre-Robin sequence, Goldenhar syndrome), periglottic edema (e.g., following rigid bronchoscopy), recurrent laryngeal nerve injury (e.g., following thyroid surgery), maxillofacial trauma, or OSA. Some of the more important of these conditions are discussed in the following paragraphs.

ANGIOEDEMA

Angioedema (former term: angioneurotic edema) is a rapid form of tissue swelling mediated by anomalous activation of the complement system with release of histamine and other inflammatory mediators.[58] It is usually the result of an allergic reaction. Hereditary angioedema is a variant family that arises from an autosomal dominant genetic mutation. Complete loss of the airway can occur in severe cases of either form. Just as with anaphylaxis, epinephrine may be lifesaving when the cause of angioedema is allergic, but treatment with epinephrine is not helpful in cases of hereditary angioedema.[59] Intubation of the trachea is often required in affected patients, usually during topical anesthesia with the patient awake or lightly sedated.

ACUTE EPIGLOTTITIS

Epiglottitis, an inflammatory disease of the epiglottis, arytenoids, and aryepiglottic folds, is among the most dreaded of airway-related infections, especially in the pediatric population.[60-64] In the past, victims were usually children 2 to 6 years of age, who were often infected with *Haemophilus influenzae*. Today, a vaccine against *H. influenzae* has reduced the frequency of this tragic affliction. The clinical presentation often includes a sore throat, dysphagia, muffled voice, and fever. Difficulty with swallowing leading to drooling from the mouth may occur. Victims may appear to be systemically ill ("toxic") and assume an open-mouth "tripod" position to ease breathing. Stridor, respiratory distress, and complete airway obstruction may occur. The chief differential diagnosis in children is laryngotracheobronchitis (croup).[65,66]

Examining the child's airway at the bedside may exacerbate the condition, and anything that could bring the child to cry (e.g., needles) should be avoided when possible. A common management approach involves careful inhaled induction of anesthesia using sevoflurane with the child sitting in the anesthesiologist's lap. Then oral intubation of the trachea can be performed using a smaller than usual tracheal tube. The child should receive "deep" anesthesia but should still be breathing spontaneously. Intravenous access and full monitoring should be established as anesthesia is deepened. If at laryngoscopy the airway cannot be identified, one trick is to have someone compress the child's chest, thus generating a small air bubble in the glottis that the person performing the anesthetic can aim for in the trachea. Failure to secure the airway in this manner may necessitate rescue through rigid bronchoscopy, by establishing a surgical airway, or by other means. In the past these children were often then managed by tracheostomy; however, contemporary management usually includes intensive care unit (ICU) admission, throat and blood cultures, conversion to nasotracheal intubation, and intravenous antibiotic therapy.

Epiglottitis can also occur in adults.[67] The first president of the United States, George Washington, is said to have died of it, although being repeatedly phlebotomized (as was the custom of the day) undoubtedly contributed to his demise. Here the situation is less ominous because the adult airway is larger. In cooperative adults, cautious oropharyngeal examination and fiberoptic nasopharyngoscopy help assess the degree of disease. The current consensus is that many adults can be adequately treated in an ICU with inhaled mist, antibiotics, and corticosteroids, and that tracheal intubation is necessary only if symptoms of respiratory distress develop. Should intubation be needed, awake fiberoptic laryngoscopy is probably the best way to secure the airway in cooperative adults, whereas the use of inhaled induction of anesthesia in adults with a compromised airway is now considered to be more perilous than was once thought.

RETROPHARYNGEAL ABSCESS

Retropharyngeal abscess formation may occur from bacterial infection of the retropharyngeal space following dental or tonsillar infections.[68-74] If the condition is untreated, the posterior pharyngeal wall may advance anteriorly into the oropharynx, with resulting dyspnea and airway obstruction. Other clinical findings may include difficulty in swallowing, trismus, and a fluctuant posterior pharyngeal mass. An abscess cavity may be evident on lateral neck radiographs, and anterior displacement of the esophagus and upper pharynx may be present. Airway management may be complicated by trismus or partial airway obstruction. Because abscess rupture can lead to tracheal soiling, contact with the posterior pharyngeal wall during laryngoscopy and intubation should be minimized. Incision and drainage are the mainstays of treatment. Tracheostomy is often, but not always, required.

LUDWIG ANGINA

Ludwig angina is a multispace infection of the floor of the mouth.[75-79] The infection usually starts with infected mandibular molars and spreads to submandibular, sublingual, submental, and buccal spaces. The tongue becomes elevated and displaced posteriorly, which may lead to loss of the airway, especially when the patient is in the supine position. As with retropharyngeal abscess, an additional concern is the potential for abscess rupture into the hypopharynx (with possible lung soiling) either spontaneously or with attempts at laryngoscopy and intubation. Airway management options depend on clinical severity, imaging findings (e.g., computed tomography [CT] or magnetic resonance imaging [MRI] findings), and surgical preferences, but elective tracheostomy before incision and drainage remains a classic, if dated, treatment modality.[79] Most experts advocate fiberoptic intubation when possible. In addition, because Ludwig angina is often associated with trismus, nasal fiberoptic intubation is frequently needed.

AIRWAY TUMORS, POLYPS, AND GRANULOMAS

Airway tumors can be benign or malignant (Figs. 70.5-70.7), but regardless of their pathologic characteristics, airway obstruction is always a potential concern.[80-83] Discussion with the surgical team concerning the size and location of the tumor, along with a review of any video-recorded nasopharyngeal video examinations, will help determine whether awake endotracheal intubation is needed. Polyps may also be found throughout the airway and can lead to partial or complete airway obstruction. Vocal cord polyps, cysts, and granulomas may result from traumatic intubation, vocal cord irritation from ETT movement, or other causes, especially in women.[84-90] Vocal cord cancer can also occur.[91] The potential also exists for exacerbation of asthma in patients with nasal polyps who receive aspirin, ketorolac (Toradol), and other nonsteroidal antiinflammatory drugs (NSAIDs) (the Samter triad).[92,93]

LARYNGEAL PAPILLOMATOSIS

Patients with laryngeal papillomatosis caused by human papillomavirus (HPV) infection may require frequent

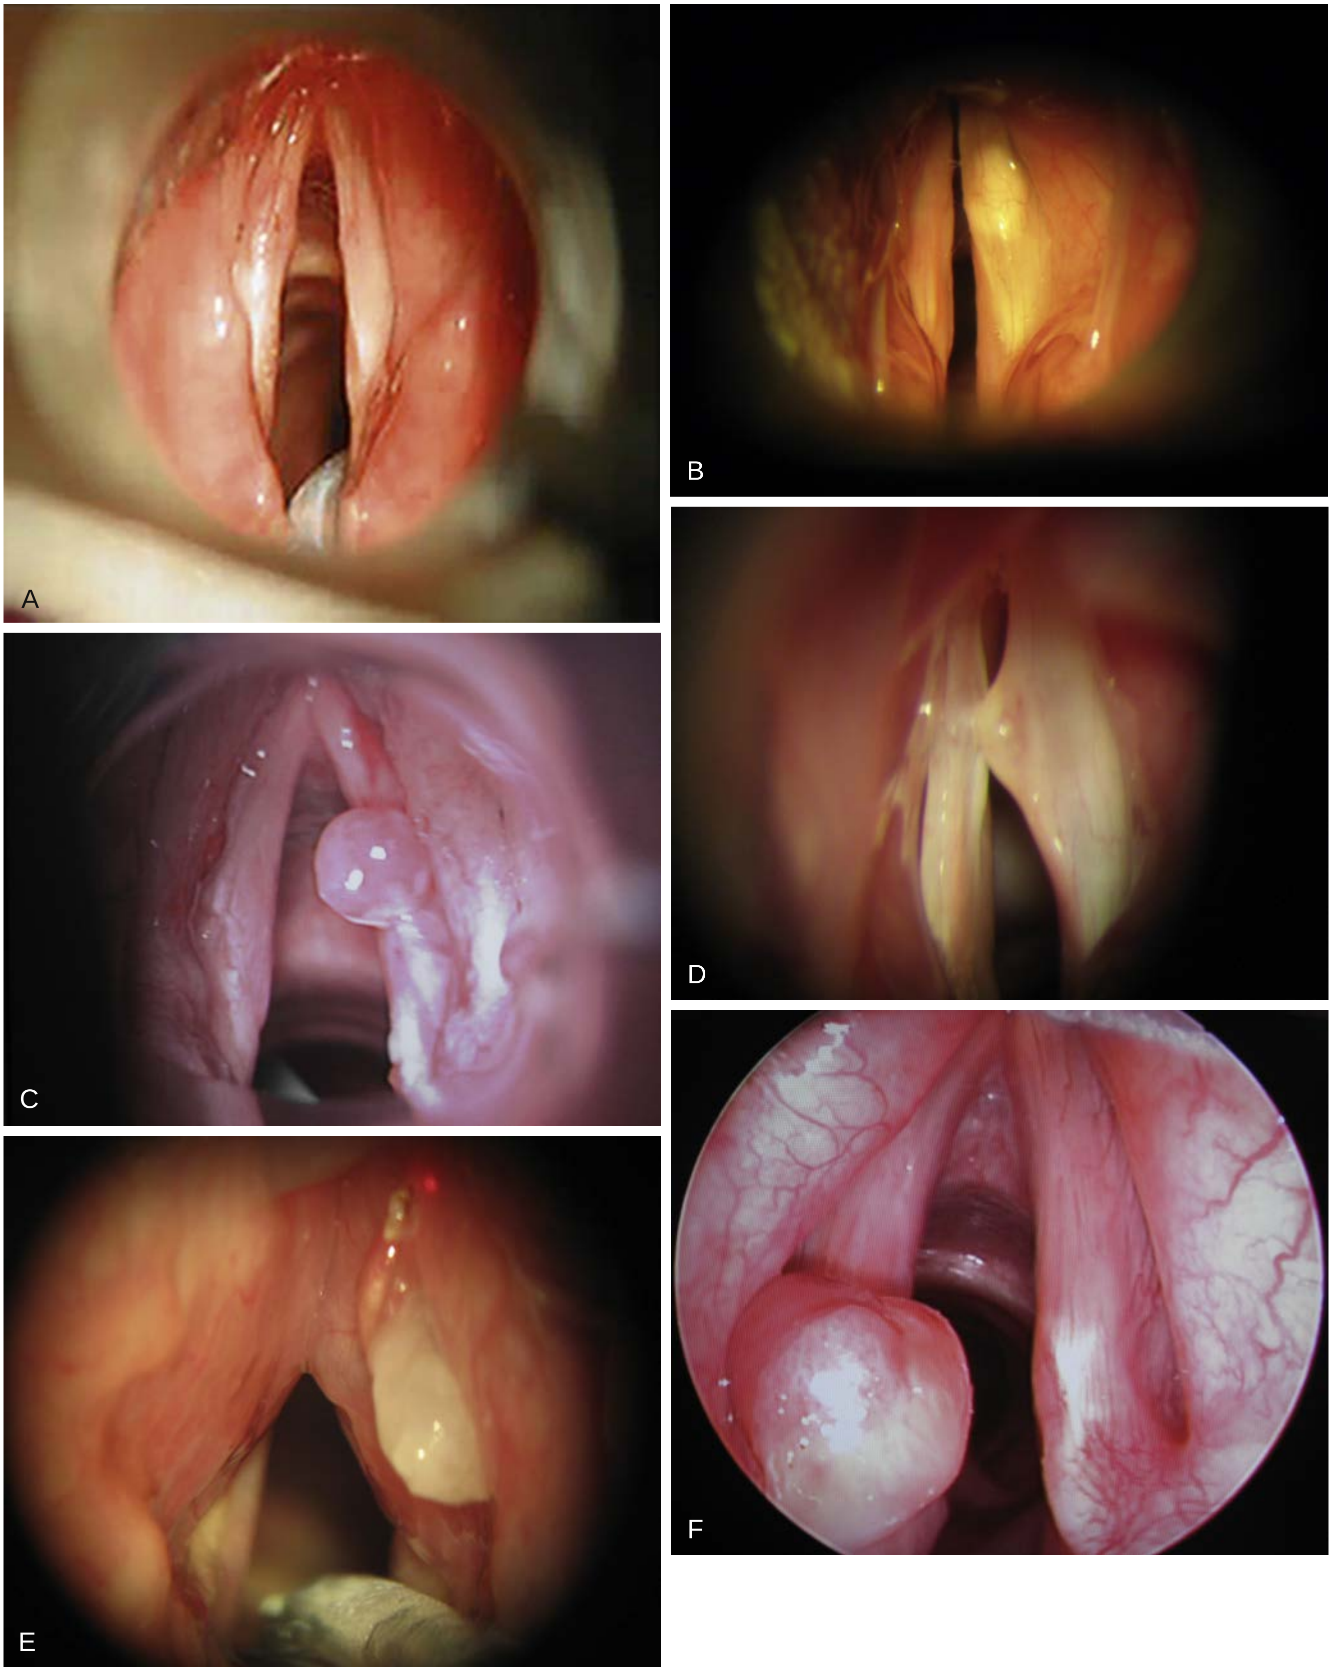

Fig. 70.5 Vocal cord lesions with little or no airway compromise. (A) Normal vocal cord. (B) Minor right vocal cord lesion. (C) Granuloma on the middle right vocal cord. (D) Kissing nodule on the right vocal cord. (E) Anterior webbing of the vocal cord. (F) Intubation granuloma. (From Feldman MA, Patel A. Anesthesia for eye, ear, nose, and throat surgery. In: Miller RD, ed. *Miller's Anesthesia*. 7th ed. Philadelphia: Churchill Livingstone; 2010:2357–2388.)

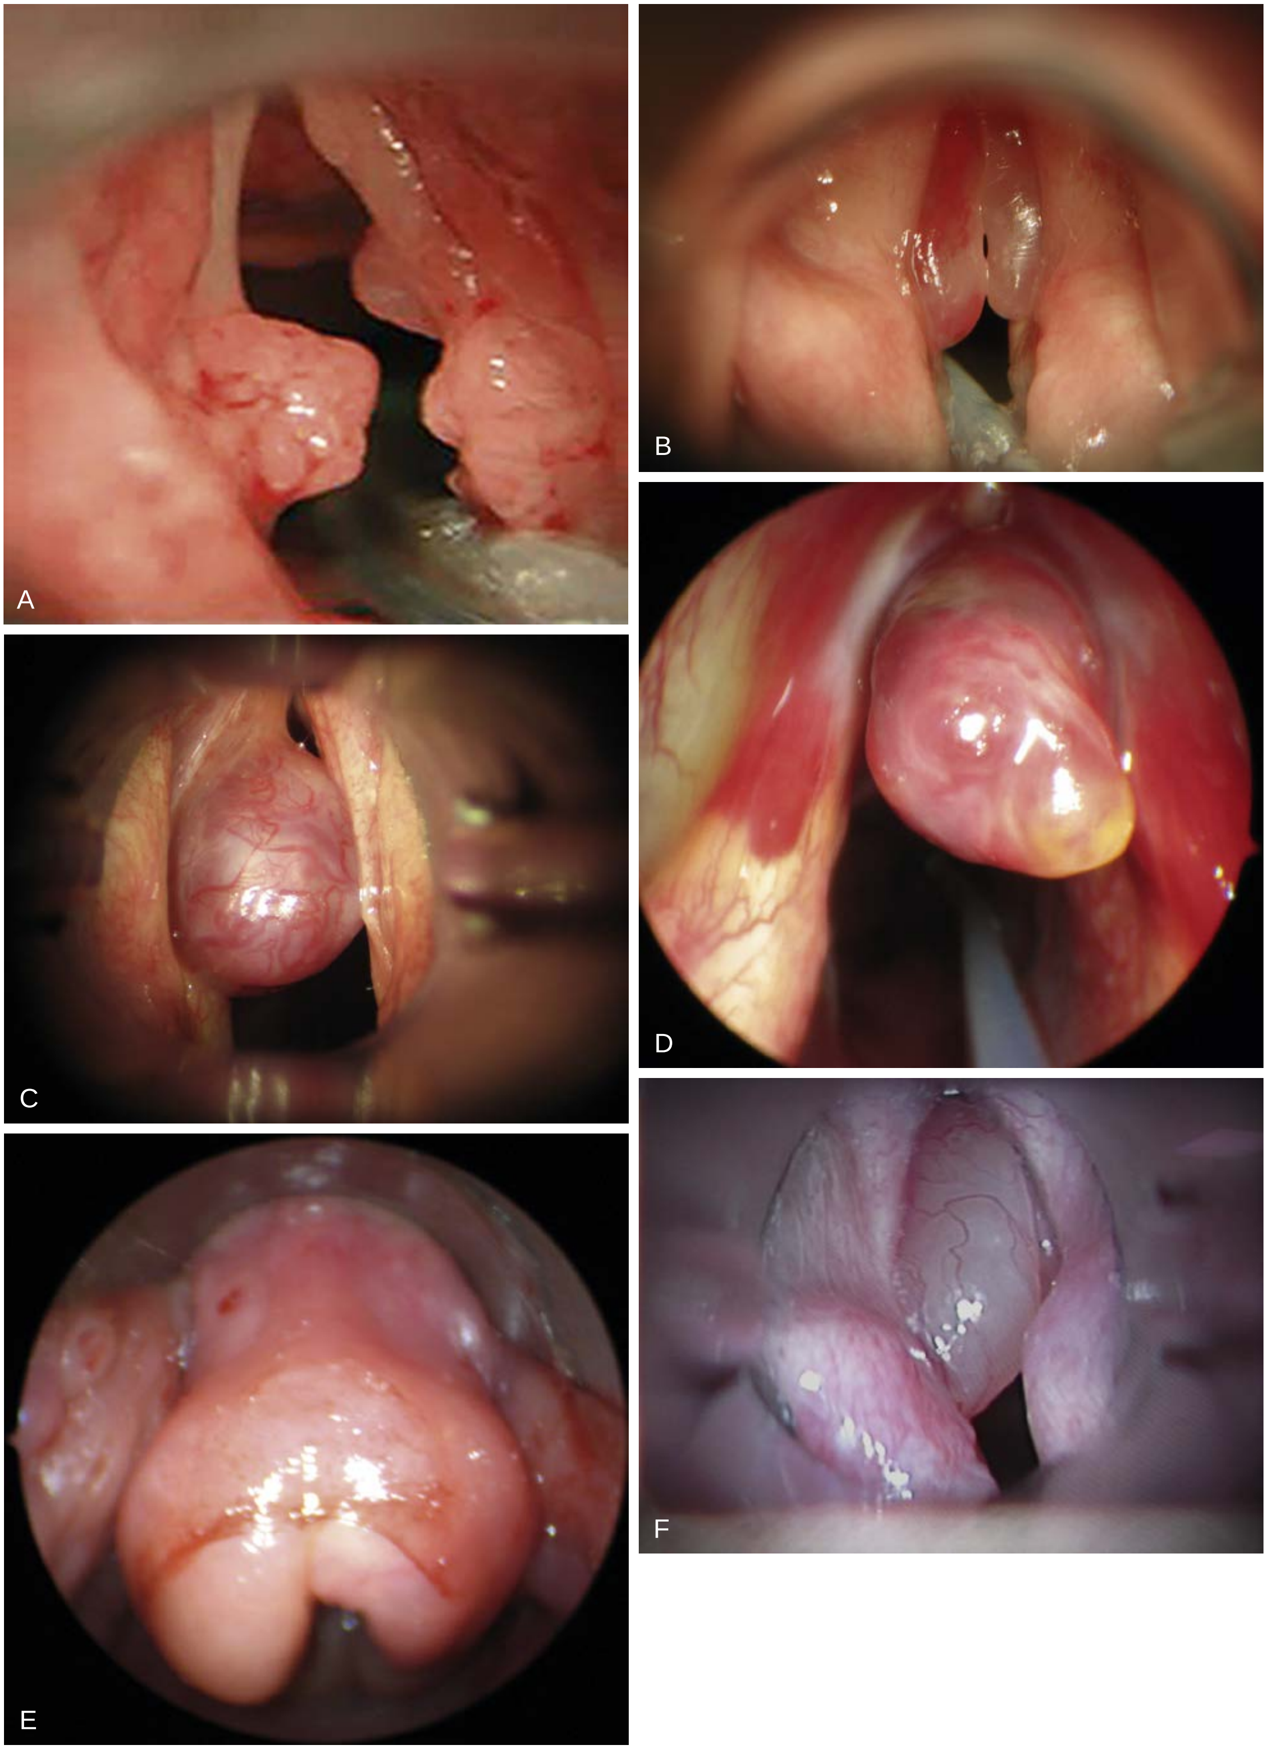

Fig. 70.6 Vocal cord lesions with significant airway compromise. (A) Papilloma of both vocal cords. (B) Bilateral Reinke edema. (C) Left vocal cord polyp. (D) Anterior glottic granuloma. Philadelphia: Churchill Livingstone; 2010:2357–2388.)

application of laser treatment for attempted papilloma eradication.[94-99] In some cases the airway may be close to obstruction because of an overgrowth of lesions. During laser treatment, inspired oxygen concentration should be kept to a minimum, with the avoidance of nitrous oxide, to reduce the chance of an airway fire. After treatment, the airway is raw and edematous. Laryngotracheomalacia may occasionally be present, sometimes leading to complete upper airway collapse following extubation of the trachea.

Anesthesia for Panendoscopy

Panendoscopy, sometimes known as triple endoscopy, involves three diagnostic components: laryngoscopy, bronchoscopy, and esophagoscopy. Such procedures and others involving the larynx, pharynx, or trachea often require specialized ENT laryngoscopes, frequently in conjunction with a small-diameter ETT or a tube specifically designed for laser surgery. Panendoscopy is used in patients with head and neck cancer to search for vocal cord lesions, obtain tissue biopsies, monitor for tumor recurrence, and so on. In such cases, one should consider the following specific issues in discussion with the surgical team: what is the anticipated pathologic process, and how is it expected to affect intubation or ventilation? (In some cases the patient's disease may not allow the use of an ETT, so that jet ventilation or a rigid bronchoscope is needed.) What is the plan for airway management, and how does it affect the delivery of anesthesia? How does the presence of coexisting disease

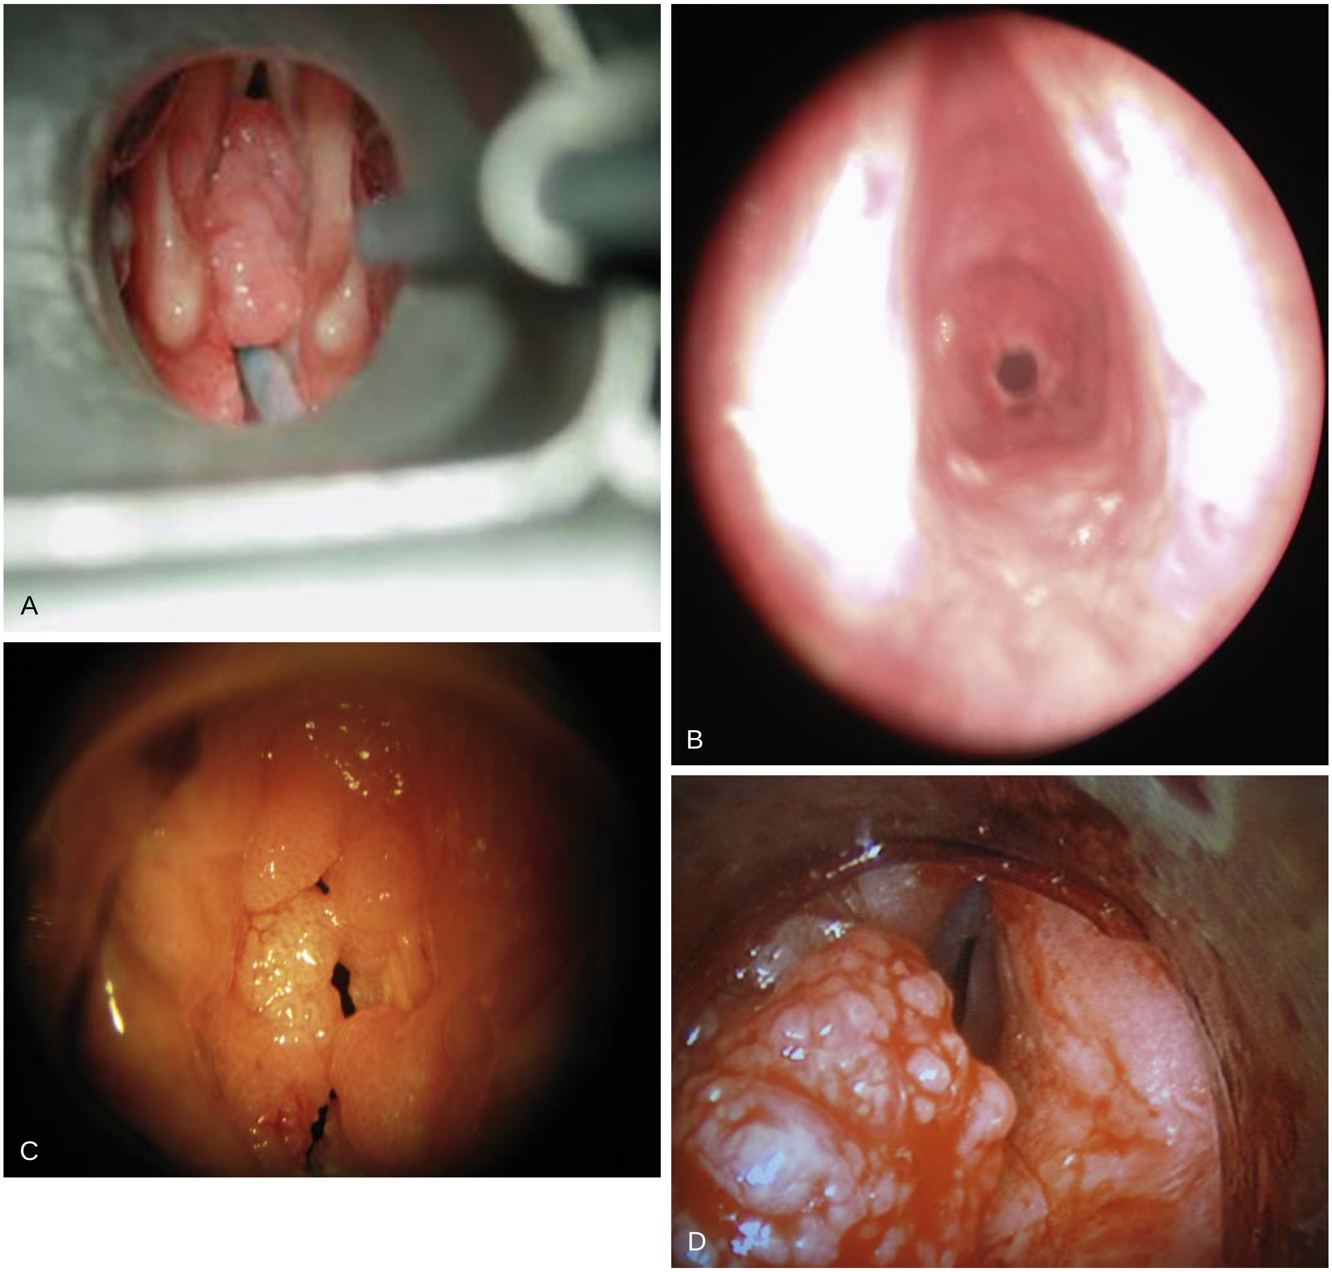

Fig. 70.7 Vocal cord lesions with severe airway compromise. (A) Papilloma of vocal cord. (B) Severe subglottic stenosis (2-mm airway). (C) Bilateral papilloma. (D) Extensive supraglottic carcinoma.

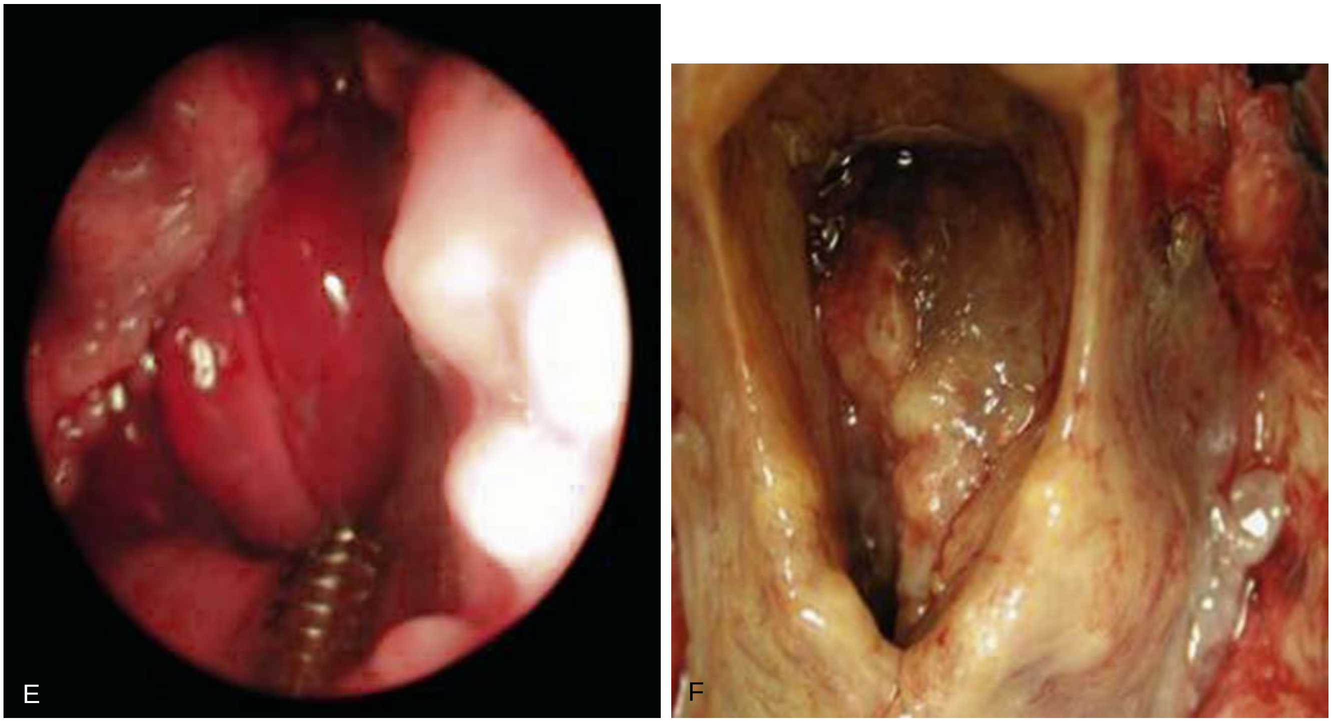

Fig. 70.7, cont'd (E) Acute epiglottitis. (F) Laryngeal carcinoma. (From Feldman MA, Patel A. Anesthesia for eye, ear, nose, and throat surgery. In: Miller RD, ed. *Miller's Anesthesia.* 7th ed. Philadelphia: Churchill Livingstone; 2010:2357–2388.)

(e.g., coronary artery disease, chronic obstructive pulmonary disease, gastroesophageal reflux disease) affect management? What specialized equipment may be needed? (For example, when airway obstruction is present, the surgeon may employ dilatational balloons, lasers, or a microdébrider to open up the airway.)

Five airway options for panendoscopy exist: (1) use of an ETT, typically a narrow-bore MLT that provides the surgeon with a superior glottic view; (2) jet ventilation in conjunction with a rigid ENT laryngoscope, without the use of an ETT; (3) hybrid methods, such as the intermittent use of an SGA or an MLT tube in conjunction with a rigid laryngoscope, jet ventilation, or intermittent apnea; (4) tracheostomy using local anesthesia before inducing general anesthesia; and (5) elective placement of a specially designed transtracheal jet ventilation cannula (e.g., Ravussin jet ventilation catheter before induction[100]). The last two options are only occasionally used for patients with a suspected difficult airway; awake tracheal intubation is the most common approach in patients with a difficult airway. Moreover, when jet ventilation is used, total intravenous anesthesia (TIVA), for example with infusions of propofol and remifentanil, is needed. Finally, when panendoscopy is combined with laser surgery, a laser-safe ETT is often used.[101,102]

Panendoscopy is generally done while the patient is under general anesthesia with the patient's neck flexed and the head extended, usually employing a shoulder roll and a head ring (Jackson position). Typically, an anterior commissure laryngoscope is used and fixed into position by suspension (Fig. 70.8). This technique allows the surgeon's hands to be free and the operating microscope to be used. Other specialized ENT surgical laryngoscopes that are commonly used, often in conjunction with a microscope for laryngeal microsurgery, include the Dedo laryngoscope (Elmed, Addison, IL) and the Universal Modular Glottiscope (Endocraft, Providence, RI). Here, once the laryngoscope is correctly configured ("suspended"), the surgeon brings the operating microscope into the field and uses a variety of microlaryngeal instruments to treat the patient.

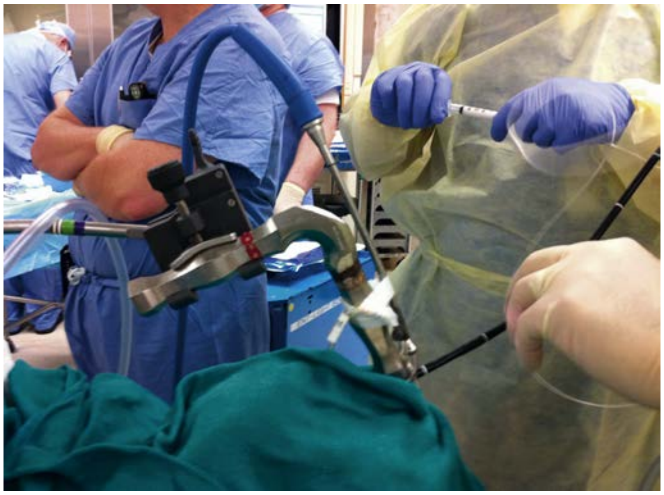

Fig. 70.8 Patient undergoing an ear, nose, and throat procedure using a suspended anterior commissure laryngoscope. A jet ventilation attachment is taped to the handle. A fiberoptic bronchoscope with a laser fiber is in use to deliver laser pulses to areas of pathologic tissue. (Image courtesy Dr. Basem Abdelmalak, Cleveland Clinic.)

A variety of anesthetic techniques can be used for panendoscopy procedures. The most common approach is to perform the procedure while the patient is under general anesthesia with muscle relaxation in conjunction with an MLT-type tracheal tube (Fig. 70.9). This technique is

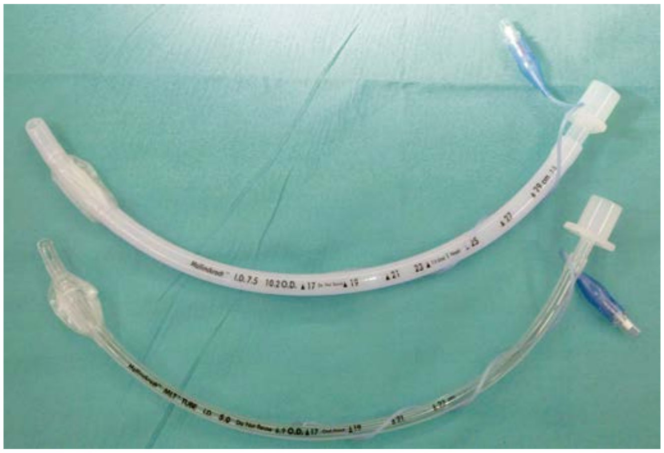

Fig. 70.9 Regular 7.5-mm inner diameter *(ID)* tracheal tube *(top)* in comparison with a 5.0-mm ID microlaryngeal *(MLT)*–type tracheal tube *(bottom)*. The MLT tube has a narrow lumen that provides the surgeon with improved glottic exposure at the cost of higher ventilation pressures.

familiar to anesthesiologists, provides both airway protection and control of ventilation, allows for reliable capnographic carbon dioxide (CO_2) measurements, and allows for the use of volatile anesthetics without operating room pollution. Disadvantages of the technique include higher than usual ventilation pressures as a consequence of the tube's narrow diameter, somewhat hindered surgical access, and concerns for tube ignition when a laser is in use.

Because a tracheal tube may impair access to some glottic structures, however, some cases are performed using intermittent apnea during general anesthesia and administration of neuromuscular blocking drugs. Disadvantages of this technique include the need for a TIVA technique, the need for repeated intubation-extubation cycles (potentially producing glottic trauma), fragmentation of the surgical work into brief apneic segments, and the repeated interruption of ventilation and oxygenation.

Next, panendoscopy is often performed using supraglottic jet ventilation.[103,104] This technique requires TIVA and entails some special issues because it involves the delivery of high-pressure oxygen pulses (typically 20-50 psi in adults, frequently delivered 1 second on/3 seconds off), usually through an adapter that attaches to the surgical laryngoscope. Additionally, subglottic methods (e.g., using a Hunsaker catheter[105,106]) and transtracheal methods of jet ventilation[107-110] have been described. Each pulse of oxygen entrains room air, thus increasing the gas volume delivered and diluting the oxygen concentration (Venturi effect). Disadvantages of jet ventilation include the need for TIVA, the potential for barotrauma (remember that a pressure of 50 psi is equivalent to 3515 cm H_2O), an inability to measure either end-tidal CO_2 ($ETCO_2$) or tidal volume easily, and the fact that the technique is often suboptimal in obese individuals. Finally, a variant of jet ventilation known as high-frequency jet ventilation is sometimes used in these cases,[111,112] often in conjunction with a special ventilator, an intratracheal catheter, and transcutaneous CO_2 monitoring.

Otolaryngologic Trauma

Although the topic of anesthesia care for the trauma patient is the subject of Chapter 66,[113] a few special points pertaining to patients who have undergone head and neck trauma should be emphasized. First, patients with head and neck trauma may have a concurrent brain injury or injury to the cervical spine. Until cleared of a possible cervical spine injury, patients should be placed in a rigid cervical collar. In addition, although placing the patient's head in the customary "sniffing" position can facilitate laryngoscopy, this technique is contraindicated in patients with a suspected cervical spine injury for fear of exacerbating any injury. Additionally, jaw thrust and chin lift maneuvers can be more difficult when a cervical collar is used or when comminuted mandibular fractures are present.

Second, facial injuries can produce extensive bleeding, as well as the aspiration of blood, bone, cartilage, teeth, and tissue fragments. Third, the airway may be compromised, especially when bilateral mandibular fractures are present. Airway trauma from blunt or penetrating injuries, burns, inhalational injury, or even iatrogenic causes may be present. Immediate airway management options include orotracheal intubation (awake versus rapid-sequence induction), a surgical airway carried out using local anesthesia, or even intubation through an open airway in cases of tracheal transection. Oropharyngeal airways may not be tolerated in patients with an intact gag reflex, and inserting a nasopharyngeal airway may exacerbate bleeding.

Although fiberoptic intubation would seem to offer many advantages in trauma cases, clinical experience suggests otherwise, at least in some cases, because navigating through a distorted airway filled with blood and foamy secretions challenges even the most experienced bronchoscopists. Special concerns exist when the trachea is intubated in a patient with laryngeal trauma because this may result in further injury or even complete airway loss (e.g., in the event of inadvertent ETT placement through a laryngeal fracture into the mediastinum). Clinical findings suggestive of laryngeal trauma include abrasions, discoloration, indentation, bleeding, or pain in the region of the larynx, as well as dyspnea, dysphagia, dysphonia, stridor, hemoptysis, subcutaneous emphysema, and hoarseness. Signs of pneumothorax may also be present, whereas fiberoptic endoscopic examination may reveal edema, the presence of bleeding or hematoma, or abnormal vocal cord function. If endotracheal intubation is attempted in this setting, a fiberoptic bronchoscope with a small-diameter ETT can be used carefully, bearing in mind the foregoing concerns about fiberoptic intubation in the trauma setting. Additionally, positive-pressure ventilation by mask or SGA in this setting may worsen any subcutaneous emphysema. A tracheostomy may be the most prudent course in some cases. Finally, the application of cricoid pressure in blunt laryngeal trauma may result in cricotracheal separation and so is contraindicated. In any event, in both facial trauma and airway trauma, initial management is dictated by the degree of respiratory distress or potential airway compromise, the available equipment, and clinical preferences.

Midfacial fractures deserve special mention. These fractures are defined by the Le Fort classification. A Le Fort I

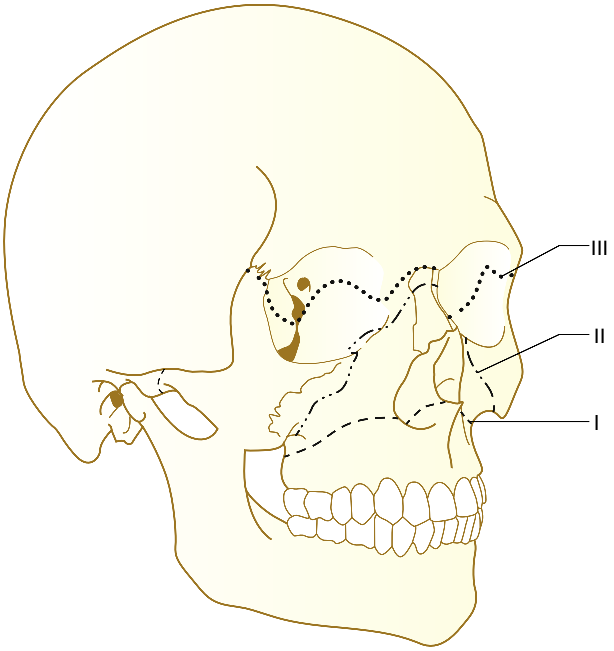

Fig. 70.10 Classification of midfacial fractures. Le Fort I: alveolar fracture. Le Fort II: zygomatic-maxillary complex fracture. Le Fort III: cranial facial dysostosis with separation of the midface from the skull. (From Schuller DE, Schleuning AJ. *Otolaryngology: Head and Neck Surgery.* 8th ed. St. Louis: Mosby; 1994:157.)

fracture is a horizontal fracture that involves the inferior nasal aperture, separating the maxillary alveolus from the rest of the midfacial skeleton. Le Fort II fractures are pyramidal nasomaxillary fractures that break from the upper craniofacial skeleton. Le Fort III fractures, less commonly encountered than the others, involve the separation of the facial skeleton from the skull base. These fractures are illustrated in Figure 70.10.

Nasal Surgery

Nasal surgery can involve external procedures, procedures within the nasal cavity, surgery involving the nasal bones, and nasal sinus surgery. Besides the usual concerns, preoperative assessment should focus on the suitability of topical nasal vasoconstrictor use, the possibility of undiagnosed OSA, and the potential presence of the Samter triad (nasal polyps, asthma, and a sensitivity to aspirin and NSAIDs that may produce deadly bronchospasm). Because postoperative bleeding is a common complication after nasal surgery, patients should not be taking NSAIDs and aspirin for 1 to 2 weeks preoperatively.

Preoperative planning begins by deciding whether the procedure is best performed with local (usually accompanied by intravenous sedation) or general anesthesia. Although local anesthesia may be suitable for simple procedures such as cauterization or straightforward polypectomy or turbinectomy surgery in adults, often general anesthesia is required. When general anesthesia is chosen, a choice must then be made among a simple facemask (as may be appropriate for pediatric myringotomy surgery), an SGA device (e.g., flexible LMA), and a tracheal tube (e.g., an unkinkable wire-reinforced design). This decision should be made jointly with the surgeon. Although the use of an SGA during ENT surgery has its enthusiasts, negative experiences, such as airway obstruction related to device malpositioning, have led many clinicians to prefer a tracheal tube in such cases.

Patients undergoing rhinoplasty are typically young, healthy individuals requiring reconstruction of the external nose for deformity treatment.[114,115] Septoplasty (correction of a deviated septum)[116-118] and surgery to remove nasal polyps[119,120] are often performed to improve nasal airflow and ventilation of the sinuses. Some malignant lesions require excision of the entire nose with follow-up staged reconstruction using a forehead flap. Open nasal fracture reduction procedures are usually performed after the initial swelling has resolved; if the injury is corrected too late, the bones can be difficult to align and can lead to significant surgical bleeding. General endotracheal anesthesia is usually carried out in such cases, often using a midline reinforced ETT taped to the chin. In closed nasal fracture reduction, the surgeon applies forceful pressure to realign the nasal bones, a procedure that usually takes only a few seconds but nevertheless is so intensely painful that the procedure is usually preceded by a single induction dose of propofol, followed by airway support as needed as a nasal cast is applied. However, when the reduction is expected to be bloody or otherwise complicated, the airway is usually protected with an ETT or an SGA device. In many of these procedures, nasal packs, stents, and/or casts are placed; nasal stents offer an advantage over packs in that one can breathe through them.

In many ENT cases, a "throat pack" made of a long piece of saline-soaked gauze is stuffed around the ETT to prevent blood and surgical debris from entering the pharynx and larynx. Typically, a few inches of gauze are kept outside the mouth as a reminder of its presence, because an inadvertently retained pack can lead to catastrophic airway obstruction after extubation.[121] In addition to suctioning, many clinicians follow throat pack removal with pre-extubation laryngoscopy and a neck flexion-extension maneuver to encourage any residual clot (the so-called "coroner's clot") to fall past the soft palate into a position where it can be removed under direct vision.

Gentle awakening in nasal surgery is important because coughing and bucking on emergence frequently produce undesirable bleeding. Techniques that are often helpful include the use of a remifentanil infusion and the application of lidocaine down the ETT with the cuff temporarily deflated while the patient is still under deep anesthesia. Oral and gastric suction before emergence will decrease the incidence of postoperative nausea and vomiting (PONV). When nasal packing is used, patients should be advised before induction of anesthesia that, on emergence, they should breathe through the mouth. On awakening, applying pressure on the nose with a facemask should not be done for fear of ruining the surgeon's handiwork. In addition, all postoperative patients with nasal packs will have obstructed nasal passages unless nasopharyngeal airways are incorporated into the nasal pack, and patients with OSA are in particular need of careful postoperative respiratory monitoring. Finally, postoperative pain in these procedures usually does not require opiates, and the use of oral acetaminophen and an NSAID usually suffices.

In many of these procedures, a topical vasoconstrictor such as phenylephrine, oxymetazoline, or cocaine is used. Although these topical agents are important drugs that reduce bleeding and improve visualization during nasal and endoscopic procedures, they sometimes produce cardiovascular toxicity.[122] The cardiovascular effects of cocaine, usually administered as a 4% (40 mg/mL) topical solution, result from the drug's blocking the reuptake of norepinephrine at sympathetic nerve terminals. Consequently, cocaine would not be a first-choice vasoconstrictor in patients with coronary artery disease or hypertension, or in patients taking monoamine oxidase inhibitors.[123] When cocaine use is appropriate, the dose should not ordinarily exceed 1.5 mg/kg.

Phenylephrine is an α-adrenergic agonist topical vasoconstrictor either used alone or in combination with lidocaine. The initial dose should not exceed 500 μg (<20 μg/kg in children ≤25 kg). Because severe hypertension sometimes results following phenylephrine use, blood pressure monitoring is particularly important. Instances of unacceptable hypertension should be treated with direct vasodilators or α-receptor antagonists; the use of β-adrenergic and calcium channel blockers should be avoided because they may worsen cardiac output and produce pulmonary edema.[124]

Oxymetazoline, a selective α_1-agonist and partial α_2-agonist imidazoline-derivative, is perhaps the most popular topical vasoconstrictor in ENT surgery, primarily because of its excellent safety profile and availability as an over-the-counter product.[125-127] Three sprays of 0.05% solution are administered in each nostril. This drug should be avoided in patients taking monoamine oxidase inhibitors. However, despite its relative safety, complications have been reported.[128,129]

Tonsillectomy and Adenoidectomy

The adenoids are a mass of lymphoid tissue located posterior to the nasal cavity, in the roof of the nasopharynx. If this tissue becomes hyperplasic, nasopharyngeal obstruction and a number of related problems can occur such that the adenoids merit surgical removal (adenoidectomy). When removed, the tonsils are usually taken as well. Other indications for tonsillectomy include tonsillar hyperplasia, recurrent tonsillitis, and malignant disease.[130] An especially important consideration here is that chronic oropharyngeal airway obstruction as a consequence of tonsillar hypertrophy can lead to OSA and its attendant complications (daytime sombulence, cor pulmonale, pulmonary hypertension, right ventricular hypertrophy, cardiomegaly). In addition to the usual, preoperative assessment focuses on findings suggestive of OSA, possible cardiac comorbidities, and a history of recurrent upper respiratory tract infections. The presence of a fever or a productive cough may be grounds for postponement of the surgery or for postoperative care in setting of increased vigilance (e.g., ICU or step-down facility), especially in infants.

Induction of anesthesia in adults usually entails administering intravenous drugs, whereas inhaled inductions are popular with children, followed by placement of an intravenous catheter and administration of glycopyrrolate. Oral RAE (named after the inventors Ring, Adair, and Elwyn) tracheal tubes or wire-reinforced tubes, taped in the midline to the mandible, are often preferred by surgeons and are less likely to kink following retractor placement. When a tonsillar or parapharyngeal abscess is present, the patient may have a compromised airway complicated by trismus and pharyngeal edema. Although awake abscess decompression by needle aspiration before the induction of anesthesia is sometimes done, awake fiberoptic intubation is the usual approach in this setting.

At the end of the surgical procedure, the throat pack, if previously placed, should be removed, the oropharynx should then be suctioned, and an orogastric tube should be used to empty the stomach. Extubation is sometimes performed using deep anesthesia but more commonly is carried out when the patient has intact airway reflexes. Coughing on the tracheal tube on emergence may be attenuated by the administration of lidocaine, either given intravenously or placed down the tracheal tube with the cuff temporarily deflated. Emergence on a light remifentanil infusion can also be beneficial.

Posttonsillectomy hemorrhage is a dreaded surgical emergency, especially in children.[131-133] It usually occurs within the first six postoperative hours, but it can also occur several days later. When possible, the patient should receive appropriate intravenous fluids preoperatively (including blood products when necessary). The presence of hypovolemia may dictate a reduction in induction drug dosage or the use of etomidate. Because the stomach may contain a considerable amount of blood, a *rapid-sequence induction* with cricoid pressure is usually performed with a view to protect the airway from aspiration of gastric contents. Vigorous suctioning is also needed to remove the copious oropharyngeal blood likely to be found during laryngoscopy.

Endoscopic Sinus Surgery

Endoscopic sinus surgery has become a common ENT procedure. Indications are varied and include conditions such as nasal polyposis, recurrent or chronic sinusitis, epistaxis control, tumor excision, orbital decompression (e.g., for Graves ophthalmopathy), foreign body removal, treatment of sinus mucoceles, and more.[134-136]

Proper anesthetic management helps ensure a good outcome. Considerations in such cases include local versus general anesthesia, SGA device versus ETT, and inhaled anesthesia versus TIVA, and preferences of the surgeon and anesthesiologist as well as patient comorbidities are taken into account. The most important goals are a blood-free surgical field, patient immobility, stable cardiorespiratory conditions, and gentle emergence from anesthesia. Controlled hypotension is sometimes used to improve surgical conditions; when this approach is used, intraoperative β-adrenergic blockade is associated with better operating conditions than when vasodilation drugs are administered.

Despite minimal arterial blood pressure differences, propofol-remifentanil intravenous anesthesia may provide better surgical conditions as compared with a traditional balanced technique (e.g., using an isoflurane-opiate technique), possibly because of lower heart rates and cardiac output.[137] Use of an SGA device is preferred to an ETT because of better surgical conditions and smoother emergence. However, SGA devices are prone to malpositioning and provide less protection from gastric regurgitation as compared with an ETT.[138]

The procedure typically begins with decongestion of the nose and infiltration of 1% lidocaine with 1:100,000 epinephrine, often followed by the bilateral nasal placement of pledgets soaked in 4% cocaine. In most cases, an image-guided surgical system is used; this allows the surgeon to know exactly where he or she is operating by using a preoperative CT scan. This technology allows the surgeon to visualize four different views simultaneously: the coronal, sagittal, and axial CT scan images at the same time as the real-time endoscopic view. This system requires a special headset that may preclude the use of electroencephalographic (bispectral index) monitoring.

Given the close proximity of major blood vessels and nerves, the orbit, and the brain, complications are possible, especially when the surgical landmarks are obscured by blood. Some major complications include orbital hematoma formation, blindness from orbital trauma or damage to the optic nerve, formation of cerebrospinal fluid leak, carotid or ethmoid artery invasion, entry into the cranial cavity, severe hemorrhage, and death.

Finally, not all sinus surgery is endoscopic. For example, although now largely replaced by endoscopic methods, the once common Caldwell-Luc procedure involves fenestration of the anterior wall of the maxillary sinus with surgical drainage of this sinus into the nose through an antrostomy.

Thyroid and Parathyroid Surgery

The usual indications for thyroid surgery include thyroid cancer, symptomatic thyroid goiter, and failed medical management of hyperthyroidism; the surgical procedure is almost always elective.[139] The most common indication for parathyroid surgery is hypercalcemia from hyperparathyroidism secondary to a benign parathyroid adenoma. When the hypercalcemia is severe, preoperative treatment (e.g., fluids, furosemide, bisphosphonates) may be needed.

Hyperthyroid patients should be treated preoperatively to reduce the risk of thyroid storm (thyrotoxicosis). Thyrotoxic patients may experience sinus tachycardia, atrial fibrillation, myocardial ischemia, congestive heart failure, nervousness, tremulousness, insomnia, heat intolerance, weight loss, and other findings.[140,141]

Large goiters may result in deviation of the larynx, tracheal compression leading to considerable airway narrowing, Horner syndrome, or superior vena cava obstruction, especially with retrosternal extension.[142,143] Preoperative airway evaluation by endoscopic examination and by CT is often useful to determine the extent of the disease and the possibility that sternotomy will be needed.

General anesthesia with tracheal intubation and muscle relaxation is usually employed, although many surgeons routinely use a nerve integrity monitor (NIM) ETT for neuromonitoring,[144-146] in which case neuromuscular blocking drugs must be avoided in the postintubation period. Gentle emergence from anesthesia is necessary to avoid coughing on the ETT and the possibility of hematoma formation from venous engorgement. The use of a small-dose remifentanil infusion (0.01-0.05 μg/kg/min) in the extubation period is a popular means to diminish coughing on the ETT. Although deep extubation also reduces the incidence of bucking and straining, many clinicians avoid this technique wherever possible because of airway obstruction.

Possible complications of thyroid and parathyroid surgery include hematoma formation (possibly resulting in airway impairment), vocal cord dysfunction from recurrent laryngeal nerve injury, pneumothorax, and other conditions. In patients with compressive goiters, postthyroidectomy tracheomalacia may occur following goiter excision. In postoperative patients who have undergone parathyroid and total thyroidectomy, serial calcium levels are taken to detect inadvertent hypocalcemia.

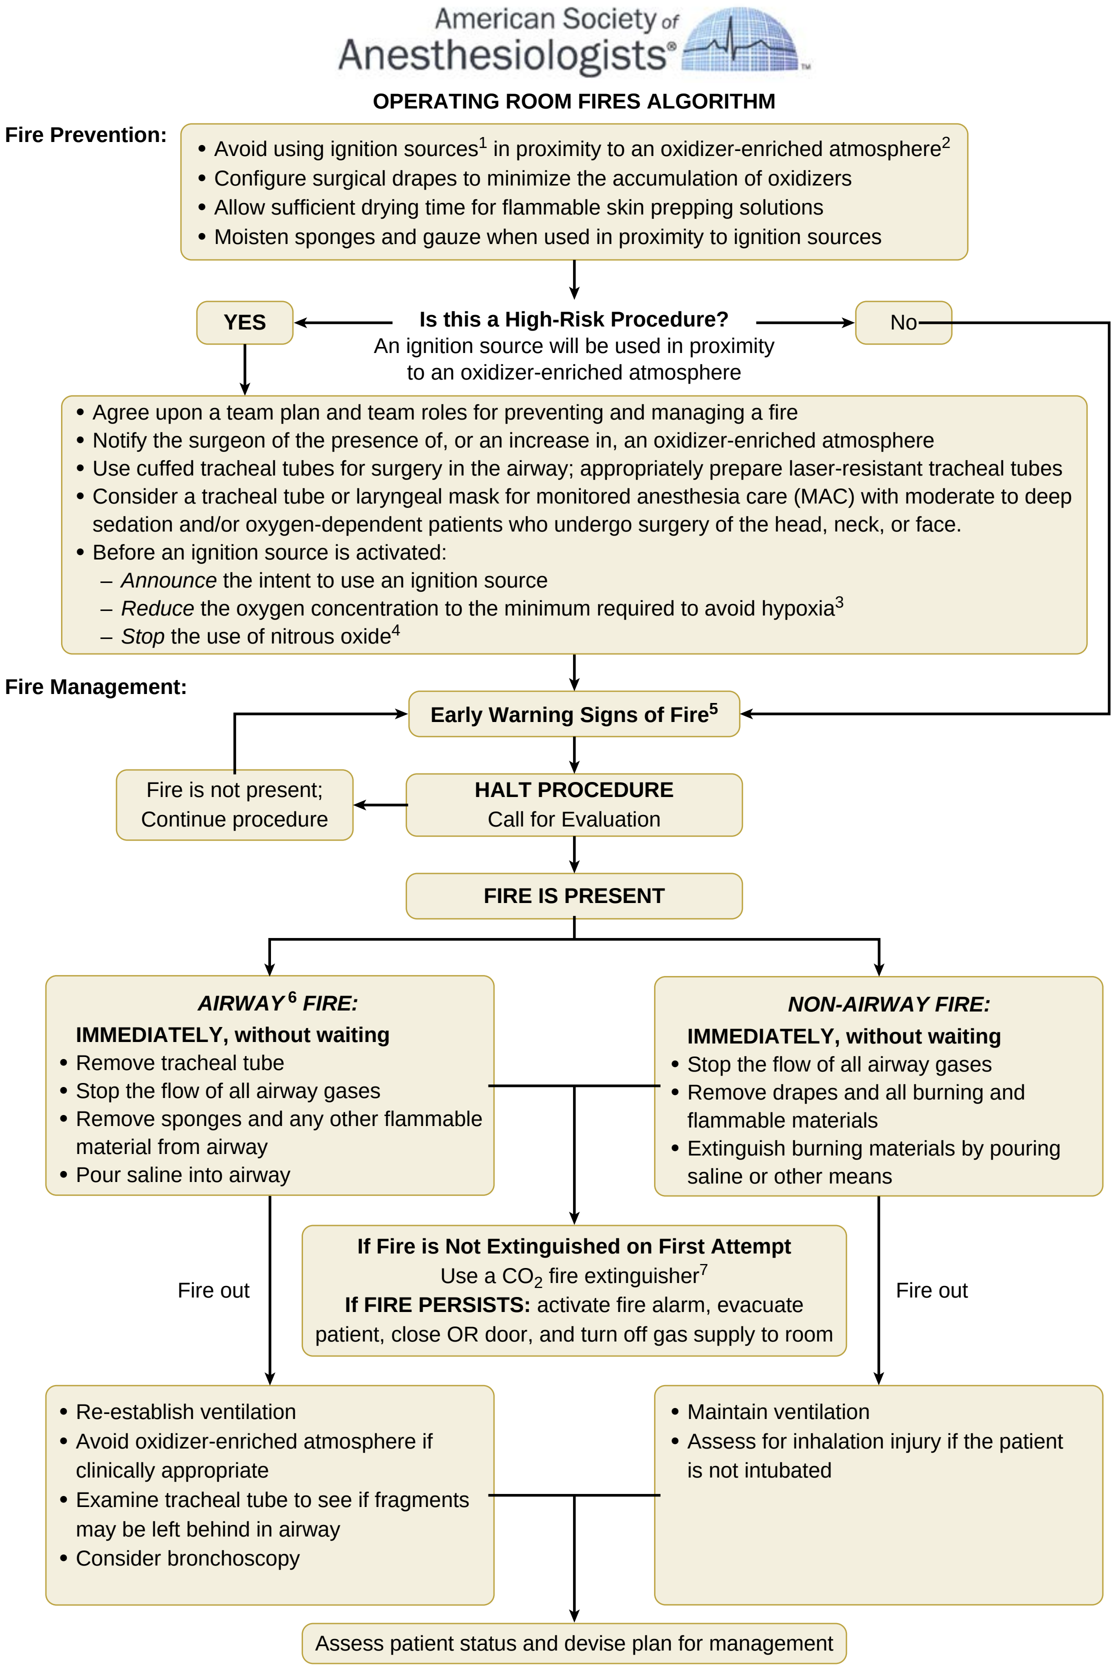
Airway Fires

An airway fire is a potentially deadly complication that may occur during tracheotomy surgery, during laser surgery to the airway, and elsewhere. For a fire to occur, the triad of fuel (e.g., ETT, drapes, sponges), oxygen, and an ignition source (e.g., laser or electrocautery) is needed. The ASA published an Operating Room Fires Algorithm (Fig. 70.11),[147] to which the reader is referred. An additional helpful resource is a checklist developed by Dr. B. Abdelmalak (Box 70.2). Prevailing conventional wisdom, at least until recently, holds that cases of airway fire call for immediate removal of the ETT. Although this is a reasonable rule of thumb, it should also be noted that in some patients removal of the ETT would result in irreversible loss of the airway. Clinicians in such a setting face a particularly difficult choice: leave the ETT in place and risk fire-related injury to the patient, or remove the ETT and risk deadly loss of the airway.

Ear Surgery

Ear operations range from simple, brief procedures such as myringotomy and tube placement to much more involved procedures such as skull-based surgery. These procedures are best divided into external ear procedures (e.g., removal of exostoses or foreign bodies), middle ear procedures (e.g., myringotomy, tympanoplasty, stapedectomy), mastoid operations (e.g., mastoidectomy), and inner ear procedures (e.g., cochlear implant placement). In such procedures, and especially with inner ear procedures, patients are particularly prone to PONV.

Although many simple procedures can be performed in well-selected individuals by using local anesthesia and intravenous sedation, more complex procedures, especially those requiring an operating microscope (for which immobility is essential), are usually best accomplished using general anesthesia with the presence of a secure airway. Regardless, in all such cases the anesthesiologist must consider issues such as the appropriate form of airway management, whether nitrous oxide is contraindicated, the possibility that postintubation muscle relaxants should be avoided to permit facial nerve monitoring, and the possible need for antiemetic prophylaxis. Most patients require a tracheal tube; the unkinkable,



American Society of Anesthesiologists®

OPERATING ROOM FIRES ALGORITHM

Fire Prevention:

- Avoid using ignition sources[1] in proximity to an oxidizer-enriched atmosphere[2]
- Configure surgical drapes to minimize the accumulation of oxidizers
- Allow sufficient drying time for flammable skin prepping solutions
- Moisten sponges and gauze when used in proximity to ignition sources

Is this a High-Risk Procedure?
An ignition source will be used in proximity to an oxidizer-enriched atmosphere

- Agree upon a team plan and team roles for preventing and managing a fire
- Notify the surgeon of the presence of, or an increase in, an oxidizer-enriched atmosphere
- Use cuffed tracheal tubes for surgery in the airway; appropriately prepare laser-resistant tracheal tubes
- Consider a tracheal tube or laryngeal mask for monitored anesthesia care (MAC) with moderate to deep sedation and/or oxygen-dependent patients who undergo surgery of the head, neck, or face.
- Before an ignition source is activated:
  - *Announce* the intent to use an ignition source
  - *Reduce* the oxygen concentration to the minimum required to avoid hypoxia[3]
  - *Stop* the use of nitrous oxide[4]

Fire Management:

Early Warning Signs of Fire[5]

HALT PROCEDURE
Call for Evaluation

Fire is not present;
Continue procedure

FIRE IS PRESENT

AIRWAY[6] FIRE:
IMMEDIATELY, without waiting
- Remove tracheal tube
- Stop the flow of all airway gases
- Remove sponges and any other flammable material from airway
- Pour saline into airway

NON-AIRWAY FIRE:
IMMEDIATELY, without waiting
- Stop the flow of all airway gases
- Remove drapes and all burning and flammable materials
- Extinguish burning materials by pouring saline or other means

If Fire is Not Extinguished on First Attempt
Use a CO_2 fire extinguisher[7]
If FIRE PERSISTS: activate fire alarm, evacuate patient, close OR door, and turn off gas supply to room

- Re-establish ventilation
- Avoid oxidizer-enriched atmosphere if clinically appropriate
- Examine tracheal tube to see if fragments may be left behind in airway
- Consider bronchoscopy

- Maintain ventilation
- Assess for inhalation injury if the patient is not intubated

Assess patient status and devise plan for management

Fig. 70.11 American Society of Anesthesiologists' Operating Room Fires (1) Ignition sources include but are not limited to electrosurgery or electrocautery units and lasers. (2) An oxidizer-enriched atmosphere occurs when there is any increase in oxygen concentration above room air level, and/or the presence of any concentration of nitrous oxide. (3) After minimizing delivered oxygen, wait a period of time (e.g., 1-3 min) before using an ignition source. For oxygen dependent patients, reduce supplemental oxygen delivery to the minimum required to avoid hypoxia. Monitor oxygenation with pulse oximetry, and if feasible, inspired, exhaled, and/or delivered oxygen concentration. (4) After stopping the delivery of nitrous oxide, wait a period of time (e.g., 1-3 min) before using an ignition source. (5) Unexpected flash, flame, smoke or heat, unusual sounds (e.g., a "pop," snap or "foomp") or odors, unexpected movement of drapes, discoloration of drapes or breathing circuit, unexpected patient movement or complaint. (6) In this algorithm, airway fire refers to a fire in the airway or breathing circuit. (7) A CO2 fire extinguisher may be used on the patient if necessary. Algorithm. *CO_2*, carbon dioxide; *OR*, operating room. (From American Society of Anesthesiologists. Practice advisory for the prevention and management of operating room fires. *Anesthesiology*. 2008;108:786–801. Copyright 2013, the American Society of Anesthesiologists, Inc. Lippincott Williams & Wilkins. Anesthesiology 2013; 118:00-00)

BOX 70.2 Management of Airway Fires

Prevention and Preparedness

1. Keep the O_2 concentration at approximately 30%, or less if possible. Use an O_2/air mixture. Avoid N_2O.
2. Use a "laser-safe" endotracheal tube.
3. Inflate the endotracheal tube cuff with dyed normal saline to provide an early indicator of cuff rupture.
4. Use a pre-prepared 50-mL syringe of saline to extinguish any fire, and flood the surgical field if a fire occurs.
5. Have an extra endotracheal tube available for reintubation in case a fire occurs.
6. Inform the surgical team working on the airway of any situation in which high concentrations of O_2 are being used.

In the Case of an Airway Fire

1. Stop lasering. Stop ventilation. Turn O_2 off (as well as N_2O if it was mistakenly in use).
2. Inform the surgical team, and assign someone to call the control desk for help.
3. Remove the burning endotracheal tube* and drop it in the bucket of water, if available.
4. Put out the fire with your improvised fire extinguisher.
5. The area should be flushed with saline.

When the Fire Is Extinguished

1. Ventilate the patient with 100% O_2 by facemask (or supraglottic airway if appropriate).
2. When the patient is stable, assess the extent of airway damage. Consider using a ventilating rigid bronchoscope; debris and foreign bodies should be removed.
3. Reintubate the patient if significant airway damage is found.
4. When appropriate, arrange for admission to an ICU.
5. Provide supportive therapy, including ventilation and antibiotics, and extubate when appropriate.
6. Tracheotomy may be needed.

ICU, Intensive care unit; *N_2O*, nitrous oxide; *O_2*, oxygen.

*Removing the endotracheal tube may be inappropriate in some cases (see text).

wire-reinforced variety is commonly used to avoid airway trouble following head rotation. Alternatively, preformed tracheal tubes (e.g., RAE tubes) are commonly used.

Nitrous oxide is avoided in middle ear procedures because it diffuses from blood to the middle ear, thereby increasing middle ear pressure and potentially distending any carefully placed tympanic membrane grafts. However, many ENT surgeons now use "underlay" grafts, in which increased middle ear pressures can actually help hold the graft in place, as opposed to older "overlay" grafts, in which a high middle ear pressure would dislocate the graft.

Many middle ear operations are performed to ameliorate hearing loss from infection or inflammation. The most frequent of these procedures, myringotomy with tube placement, is most commonly performed in children by using simple sevoflurane mask anesthesia, in conjunction with acetaminophen or (less commonly) fentanyl to treat postoperative pain. The procedure can usually be safely accomplished without establishing intravenous access.[148]

Stapedectomy, typically performed to treat otosclerosis, is usually performed using general anesthesia and may involve the use of surgical lasers (hence a potential need for laser precautions), as well as facial nerve monitoring (hence a potential need for periods with minimal neuromuscular blockade). The use of a volatile anesthetic in combination with a remifentanil infusion helps provide mild hypotension (which reduces blood loss), as well as surgical immobility. Nitrous oxide can theoretically be used early in the procedure, but it must be avoided later on to avoid damaging possible "overlay" grafts to the tympanic membrane. However, most clinicians simply avoid nitrous oxide entirely, to reduce the incidence of PONV. Gentle emergence, often involving a remifentanil infusion, helps avoid coughing or "bucking" with the tracheal tube present, with possible displacement of the bone prosthesis. Not surprisingly, extubation of the trachea during deep anesthesia is sometimes performed. Ossiculoplasty procedures involve similar considerations.

Common inner ear procedures include surgery to the cochlea, endolymphatic sac, and labyrinth. Patients with pathologic processes in the labyrinth and endolymphatic sac, such as patients with Meniere disease, often suffer from vertigo and hearing loss and are especially prone to PONV. In cochlear implant surgery, mastoidectomy is performed to implant the signal coupler while the electrode array is implanted into the cochlea, a procedure often taking over 4 hours. Considerations similar to those for stapedectomy apply, including the potential need for nerve monitoring, the avoidance of PONV, and gentle emergence from anesthesia. Some surgeons also request a degree of hypotension as a means to reduce blood loss.

Untreated chronic otitis media often leads to mastoiditis, tympanic membrane perforation, and damage to the ossicular chain. Additionally, the formation of a cholesteatoma (an invasive growth of keratinizing squamous epithelium) may spread into the mastoid cavity, inner ear, and even the brain to cause additional damage. When antibiotic treatment fails, mastoidectomy (removing infected material, draining subperiosteal abscesses, and reestablishing middle ear ventilation) may be indicated. Because blood loss can be substantial, controlled hypotension is sometimes requested. The nerve identification and gentle emergence issues discussed earlier often apply as well. Nitrous oxide is often avoided, at least in the later stages, because of the tympanoplasty component of the procedure.

Surgical procedures of the outer ear may be used to correct congenital and acquired malformations. Although these patients often present no special challenges, beware of patients whose malformation is part of Goldenhar syndrome or Treacher Collins syndrome because these patients frequently offer airway challenges. General anesthesia is typically employed, and postoperative pain can be substantial when a rib graft is used.

Parotid and Other Salivary Gland Surgery

The salivary glands comprise a pair of parotid glands, two submandibular glands, two principal sublingual glands, and a number of minor salivary glands. As exocrine glands, their function is variously to produce saliva, digestive enzymes (amylase), and lubrication, as well as to provide a bacteriostatic function. Indications for submandibular gland surgery include tumors, chronic sialadenitis refractory to medical treatment, and removal of impacted stones. The most frequent parotid disease warranting surgery is a benign neoplasm, frequently a pleomorphic adenoma. Superficial parotidectomy (complete or limited) with facial nerve dissection is the most commonly performed procedure for these lesions, although a simpler enucleation procedure is sometimes also performed.[149-151] Identification of the facial nerve and its branches, often employing nerve stimulation methods, is central to the procedure. For this reason, the surgical team usually requests that muscle relaxants be avoided after endotracheal intubation has been achieved.

Besides the usual considerations applying to all surgical patients, preoperative evaluation of patients for salivary gland surgery should consider any previous head and neck surgery and any history of radiation therapy (which can make mask ventilation difficult). The physical examination should look for tumor displacement of the airway, as well as impaired temporomandibular joint (TMJ) mobility and other predictors of airway difficulties. Available head and neck CT scans or MRI studies should be reviewed with the surgical team, with a focus on airway issues.

During these procedures, complete immobility of the patient is important. Consequently, general anesthesia with endotracheal intubation is usually required, although cases of parotid surgery performed using local anesthesia have been reported.[152] Management of the airway with an LMA for parotid surgery has been described; however, the typical 2- to 4-hour duration of the operation and the need for an operative side-up head position lead most anesthesiologists to use a tracheal tube. Sufficient anesthetic depth and patient immobility are usually achieved using relatively large doses of opioid and inhaled anesthetics, with muscle relaxants avoided to allow facial nerve monitoring for both parotid and (less commonly) submandibular surgery. I frequently employ a single, small dose of rocuronium to facilitate endotracheal intubation, followed by sevoflurane anesthesia in conjunction with a remifentanil infusion (e.g., 0.1 μg/kg/min) to provide immobility. Finally, preservation of the facial nerve is of prime importance in these operations; consequently, the surgeon often must identify the facial nerve by using a nerve stimulator. This crucial step is not possible if neuromuscular blockade is present.

Sleep Apnea Surgery

OSA involves repetitive partial or complete upper airway obstruction because of collapse of the pharyngeal airway during sleep.[153-158] This condition typically occurs despite continued movement of the diaphragm and can lead to apneas (with complete obstruction), hypopneas (with partial obstruction), and respiratory effort–related arousals. The last of these can occur without desaturation, whereas hypoxia itself leads to arousal from sleep, with reopening of the airway and the intake of a breath. Severity is related to the number of these respiratory events per hour as determined by polysomnography. Patients in whom conservative treatment (e.g., weight loss, continuous positive airway pressure, bilevel positive airway pressure, oral appliances) fails may benefit from either surgical modification of the upper airway or, rarely, tracheostomy. Commonly performed procedures include uvulopalatopharyngoplasty, uvulopalatal flap surgery, tonsillectomy and adenoidectomy, genioglossus advancement, maxillomandibular advancement, and other procedures. Sometimes these procedures are performed in combination. Possible comorbidities such as obesity, metabolic syndrome, type 2 diabetes, coronary artery disease, or cor pulmonale should be identified. Patients with OSA can be difficult to intubate tracheally or ventilate by mask, and they are especially prone to postoperative hypoxia. In addition, they frequently have conditions such as macroglossia, redundant pharyngeal tissue, lingual tonsil hypertrophy, or an anterior larynx, all of which can make direct laryngoscopy difficult.

Clinical features that increase the likelihood that OSA is present include a body mass index greater than 30 kg/m^2, large neck circumference (>17 inches in men; >16 inches in women), a high Mallampati score (3 or 4), and the presence of features such as a large uvula, macroglossia, retrognathia, tonsillar hypertrophy, or a high arched palate. The airway features that predispose to OSA may also lead to a difficult airway. For example, difficult intubation is encountered five to eight times more often in patients with OSA compared with other patients. Additionally, snoring and OSA are independent risk factors for difficult ventilation by mask.

General endotracheal anesthesia is preferable for OSA surgery because of the risk of aspiration of blood from the surgical site and the risk of laryngospasm should blood or secretions make contact with the vocal cords.

Postoperative vigilance is paramount. One reason is that patients with OSA have an increase in postoperative obstructive episodes, peaking on postoperative day 3 and returning to preoperative levels after a week. Consequently, patients with OSA who are undergoing airway surgery are not outpatient candidates. Postoperative airway edema is another concern and constitutes another reason that it is wise to minimize respiratory depressants such as opioids and sedatives postoperatively. Dexamethasone is often given to reduce airway edema.

Zenker Diverticulum

Zenker diverticulum, first described in 1874, is a herniation or outpouching of pharyngeal mucosa through the posterior wall of the hypopharynx (often between the oblique and horizontal components of cricopharyngeus).[159,160] Typically seen in the sixth to ninth decades of life and occurring in approximately 1 in 800 upper gastrointestinal barium studies, patients may describe regurgitation of undigested food when supine and food caught in the throat (i.e., in the mucosal pouch), as well as coughing, dysphagia, and halitosis. Confirmation of the clinical diagnosis is usually by barium swallow and/or endoscopy.

Surgery can be either open or endoscopic. In the open (transcervical) approach, the diverticulum is exposed through a lateral neck incision and is then resected (diverticulectomy) or tacked superiorly to the prevertebral fascia (diverticulopexy). Cricopharyngeal myotomy may be added to help prevent recurrence. In the endoscopic approach, no skin incision is required; here the surgical procedure usually involves ablating the common wall between the pouch and the cervical esophagus by using an endoscopic stapler, surgical laser, or other means.

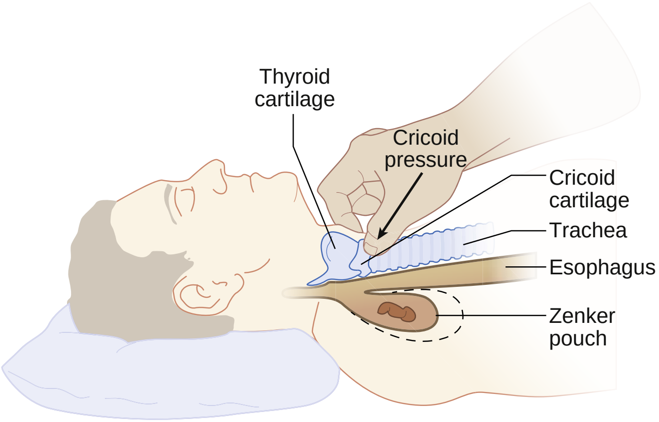

Fig. 70.12 Anatomic relationship of the diverticulum to the cricoid cartilage during application of cricoid pressure. (From Thiagarajah S, Lear E, Keh M. Anesthetic implications of Zenker diverticulum. *Anesth Analg*. 1990;70:109–111.)

Several anesthetic considerations apply. First, patients are frequently older, with applicable comorbidities, such as coronary artery disease. Second, the possibility that food caught in the pouch could end up in the airway is a concern. Additionally, oral medications such as antihypertensives administered the day of surgery may lodge in the pouch and be aspirated. Perhaps preoperative evacuation of the pouch can be performed by applying external pressure before anesthesia, but this is not commonly done because of concerns of causing iatrogenic pulmonary aspiration. More commonly, the patient is positioned with a 30-degree head-up tilt before the induction of anesthesia.

Although awake endotracheal intubation should provide excellent protection against the risk of aspiration of pouch contents, a theoretic concern exists that any coughing during the procedure, either from the use of transtracheal local anesthesia or from the instrumentation, could lead to regurgitation of pouch contents with possible aspiration. A more common technique is the use of rapid-sequence induction of anesthesia, usually with the modification that cricoid pressure is not used, for fear of discharging the pouch contents with the applied pressure. (Application of cricoid pressure is recommended only if the neck of the pouch is below the cricoid cartilage; see Fig. 70.12). Some experts have expressed the concern that using succinylcholine, especially if it is not preceded by a nondepolarizing muscle relaxant, could produce muscle fasciculations that could cause pouch compression. Even after endotracheal intubation, seepage of material around the ETT cuff can occur with surgical manipulation; some clinicians place a moist gauze throat pack to prevent aspiration of this material. Finally, the procedure is occasionally performed using regional anesthesia with deep and superficial cervical plexus blocks.

Care should be taken to avoid perforation of the diverticulum, such as with blind placement of a nasogastric tube or during difficult tracheal intubation. During the surgical procedure, retraction of the carotid sheath may stimulate baroreceptors and initiate arrhythmias, especially bradycardia, whereas significant blood loss and air embolism may occur if major vessels are accidently cut. A smooth awakening from anesthesia that is free from coughing and straining is important to avoid the risks of neck hematoma and the attendant possibility of a compromised airway.

Anesthesia for Surgical Airways: Cricothyrotomy and Tracheostomy

Two general approaches exist to create a surgical airway. In dire emergencies one may perform a cricothyrotomy,[161,162] by entering the airway through the cricothyroid membrane. This is done either by inserting a narrow-bore transtracheal ventilation catheter percutaneously through the cricothyroid membrane and employing emergency high-pressure jet ventilation or by inserting a wider-bore tube of sufficient diameter to allow low-pressure ventilation through a conventional resuscitator bag (e.g., “Ambu” bag). This second approach through the cricothyroid membrane can be achieved by using a vertical scalpel incision, identifying the cricothyroid membrane, cutting through the membrane with a horizontal stab incision, and placing (for example) a 6-mm inner-diameter tracheal tube. Alternately, one can use a commercial kit employing (for example) the Seldinger technique (e.g., Melker cricothyrotomy kit, Cook Medical, Bloomington, Ind.). An educational cricothyrotomy video is available at http://www.cookmedical.com/cc/educationMedia.do?mediaId=1522.

The second approach to achieving a surgical airway is a tracheostomy.[163,164] (Although the terms “tracheotomy” and “tracheostomy” are used interchangeably by clinicians, based on their Greek roots, the former term refers to cutting into the trachea, whereas the latter refers to the opening that has been created.) This approach is best suited for situations that are not high-level emergencies, takes rather longer to complete, and usually involves entering the airway between the second and third tracheal rings following a careful dissection of the neck tissues. Although it is very often performed using general anesthesia in an intubated ICU patient in whom ventilator weaning has failed, it is sometimes performed using local anesthesia, either employing no sedation (this is the usual case in stridulous patients, especially those requiring Heliox) or using a drug such as dexmedetomidine because of its lack of respiratory depression. In any event, the decision to perform a tracheostomy using local anesthesia is made jointly with the surgeon and depends on the extent of airway disease, the experience of the surgical team, and the degree to which the patient is able to tolerate lying supine with his or her head in extension. In some cases, the procedure must be performed with the patient in a semiupright sitting position.

In the case of patients whose tracheas are intubated, at one point in the procedure the anesthesia provider will be asked to withdraw the tracheal tube slowly to permit the airway to be entered without obstruction. Additionally, at this time the airway should be entered using a scalpel and not using cautery, to prevent an airway fire in an oxygen-rich environment.

A number of problems may arise in the postoperative period following a tracheotomy.[165-167] Bleeding, pneumothorax, subcutaneous or mediastinal emphysema, and hypoventilation or airway obstruction may occur immediately after the procedure, whereas possible late complications include tracheal stenosis, tracheoesophageal fistula formation, tracheomalacia, and even tracheal necrosis. Although posttracheotomy bleeding is usually inconsequential, bleeding into the airway may cause the patient to cough and buck forcefully. In addition, major bleeding from a large artery or vein (often the communicating branch of the superior thyroid artery) may necessitate immediate exploration of the surgical field, whereas bleeding from the innominate artery may occur from erosion by the distal end of the cannula. (One hint that the tracheostomy could be applying pressure to the innominate artery is the finding of pulsations in the tracheotomy cannula after initial insertion. Treatment includes inflating the tube cuff and pulling the tube assembly anteriorly to tamponade the bleeding. An oral tracheal tube should then be inserted for management in the operating room.)

Frequently, tracheotomy tubes must be changed, for instance because of a cuff leak or because of obstruction from the buildup of secretions. A central concern in this instance is that the replaced tube could enter a false passage rather than the trachea. (This in itself is unfavorable, but should the false passage be inadvertently ventilated, the resulting subcutaneous emphysema could eliminate the possibility of easily reestablishing the airway.) This potential problem eventually disappears as the tracheal stoma matures to form a well-defined and self-supporting orifice. However, this rigidity and tissue support are lacking in a fresh tracheostomy, so that following removal of the tracheostomy tube, the tissue may "collapse in" on itself to block the passage. Consequently, certain precautions when dealing with a fresh tracheostomy tube must be borne in mind. First, for the first week or so, tube changes should be performed in the operating room with a full set of tracheotomy instruments (e.g., cricoid hooks) and a means to intubate "from above" as a last resort if the airway is lost. Second, once the tracheotomy site has begun to mature, it is no longer necessary to carry out tube changes in the operating room, but a full set of instruments (especially cricoid hooks) should still be available. Additionally, changing the tube over a tube changer may also be useful, but some clinicians find that it may unnecessarily complicate matters. Third, before any tube change, the patient should breathe 100% oxygen. Finally, a fiberoptic bronchoscope may be potentially useful in confirming tracheal placement of a tracheostomy tube before attempting any positive-pressure ventilation that could lead to subcutaneous emphysema should the tube, in fact, be malpositioned.

Neck Dissection and Laryngectomy

Neck dissection is commonly performed in isolation or during laryngectomy to prevent or treat any local spread of head and neck malignancy.[168,169] The extent of a neck dissection operation is based on the extent to which the neck's six lymph node levels are involved, as well as on the extent to which additional structures (spinal accessory nerve, internal jugular vein, and sternocleidomastoid muscle) are removed. Depending on the degree to which the tumor can be removed and recurrence or spread can be prevented, as well as the extent that phonation and swallowing can be preserved, various surgical options are exercised. Limited disease is sometimes managed by radiation, by laser and microsurgery, or by partial laryngectomy, thus preserving organ function. In total laryngectomy, the larynx is removed in its entirety, with the airway ending in a stoma formed by bringing the cut end of the trachea to the neck surface (with the result that the trachea now becomes independent of the esophagus.) Often a perforation between the trachea and the esophagus (tracheoesophageal puncture) is made to allow eventual placement of a voice prosthesis.[170] In some cases the procedure is supplemented with microvascular free tissue transfer (free flap).

Anesthesia can be induced through a standard intravenous line, followed by large-bore intravenous and arterial lines placed after induction. A central line can usually be avoided, with systolic pressure variation of the arterial line tracing and other clinical findings to guide fluid replacement. Although nerve function monitoring is usually required during the neck dissection phase, neuromuscular blockade is acceptable at the beginning. When neuromuscular blockade is no longer desirable, opioid infusions (e.g., remifentanil) are often used to maintain adequate analgesia in conjunction with an inhaled anesthetic agent. Many clinicians prefer using a balanced technique in preference to deep inhalational anesthesia or TIVA (propofol with or without remifentanil) to avoid the troublesome hypotension. Excessive intravenous crystalloid administration should be avoided to prevent operative site edema.

In total laryngectomy cases, a tracheostomy is customarily performed near the beginning of the procedure by using a wire-reinforced ETT placed into the stoma. (Warning: accidental endobronchial intubation commonly occurs in this setting.) In some cases, the patient is turned 180 degrees from the anesthesia machine; care must be taken to ensure that nothing is disconnected in the process. Extubation in such cases is extraordinarily simple; the ETT should be removed from the stoma when extubation criteria are met. Should reintubation ever become necessary, one merely reintroduces the tracheal tube into the stoma. The patient is then simply brought to the postanesthesia care unit with an oxygen mask placed over the stoma, although when a free flap has been performed, the patient is often brought to the ICU intubated, ventilated, and sedated (depending on the surgeon's preferences and local protocols.)

Maxillary, Mandibular, and Temporomandibular Joint Surgery

Maxillectomy surgery may be limited (e.g., removal of one antral wall, such as in a medial maxillectomy), subtotal (e.g., removal of two walls of the antrum), or total (removal of the total maxilla).[171-173] Orbital exenteration sometimes accompanies the procedure should the intraorbital contents be violated by tumor. Indications for maxillectomy include the following: tumors of the maxillary sinus, palate, and other structures; some intractable fungal infections; and other conditions. The procedure is performed using general anesthesia with tracheal intubation and invasive monitoring appropriate to the patient's condition and the extent of the surgery. Although massive blood loss is unusual, precautions should be taken because hemorrhage may occur (e.g., with transection of the internal maxillary artery). Hypotensive anesthesia, when appropriate, can help reduce blood loss. Medial maxillectomy procedures conducted endoscopically do not require anything different from ordinary sinus surgery for anesthesia. When electromyography-based cranial nerve monitoring is employed, long-acting paralytic agents should be avoided.

Surgery of the mandible and TMJ may be carried out by maxillofacial surgeons, as well as by otolaryngologists and plastic surgeons.[174-176] Mandibular surgery can range from simple biopsies to all-day radical procedures involving microvascular osteocutaneous flaps. Awake nasal intubation may be required in some cases. Hypotensive anesthesia is often used for orthognathic procedures to minimize blood loss. In some cases the jaw is wired shut, and reintubation, should it be required postoperatively, can be a challenge.

TMJ dysfunction often manifests with pain and decreased mouth opening. Conditions such as osteoarthritis, synovitis, or fibrosis may be responsible. Most TMJ procedures are performed using general nasotracheal anesthesia. As with mandibular surgery, the presence of very limited mouth opening may dictate that the procedure be done with awake nasal intubation.

Ear, Nose, and Throat Laser Surgery

Lasers are commonly used in ENT surgery (Box 70.3 and Table 70.1).[177-180] The most widely used laser in ENT surgery is the CO_2 laser, which allows precise cutting with a particularly fine zone of coagulation that reduces bleeding. Tissue vaporization is particularly efficient with this laser because of the excellent absorption of the produced far-infrared photons (10,600-nm wavelength) by water present in tissue. This laser is used in the removal of laryngeal tumors and lingual tonsillar tissue, in the ablation of hemangiomas, and for the resection of some oropharyngeal malignant tumors.

Another popular laser in ENT surgery is the neodymium:yttrium-aluminum-garnet (Nd:YAG) laser, which emits photons with a wavelength of 1064 nm. These photons are poorly absorbed by water and thus tend to penetrate tissue more deeply than do those from a CO_2 laser. In addition, light from an Nd:YAG laser can be transmitted through flexible quartz fibers that can be used in conjunction with a flexible fiberoptic bronchoscope for use in treating tracheobronchial lesions.

Because surgical lasers involve high amounts of energy, they have the potential for unintended tissue damage, as well as for causing fires. Stray laser beams can ignite surgical drapes. To mitigate these risks, one should place warning signs outside the operating room, provide opaque coverings on any operating room windows, and issue protective goggles. The presence of high oxygen concentrations near the patient's face can facilitate ignition in this region, so delivering supplementary oxygen by facemask or nasal cannula requires special care. American National Standards Institute standard Z136.3 (Safe Use of Lasers in Health Care Facilities) provides additional information on this and related matters.

BOX 70.3 Some Otolaryngologic Clinical Situations in Which Laser Techniques Can Be Useful

Nose

- Turbinate reduction
- Septoplasty
- Removal of nasal obstructions, polyps, synechiae
- Treatment of rhinophyma
- Treatment of keloids and hypertrophic scars

Oropharynx and Pharynx

- Vaporization of papillomas, leukoplakias, and hemangiomas
- Tumor surgery (e.g., partial glossectomy)
- Laser-assisted uvulopalatoplasty
- Tonsillectomy

Larynx

- Removal of vocal cord polyps and granulomas
- Epiglottectomy
- Cordectomy
- Arytenoidectomy

Tracheobronchial Tree

- Treatment of tracheal stenosis
- Removal of nodules, polyps, tumors, and fibromas

Ear

- Surgery of the stapes
- Laser-assisted myringotomy
- Cholesteatoma

TABLE 70.1 A Sampling of Various Kinds of Lasers Available for Clinical Use

Type	Gas or Solid	Wavelength* (nm)	Color	Fiberoptic Transmissible?
Helium/ neon	Gas	633	Red	Yes
Argon†	Gas	500	Blue-green	Yes
CO_2	Gas	10,600	Invisible (far infrared)	No
Ruby	Solid	695	Red	Yes
Nd:YAG	Solid	1064	Invisible (near infrared)	Yes
KTP	Solid	532	Green	Yes

KTP, Potassium titanyl phosphate; *Nd:YAG*, neodymium:yttrium-aluminum-garnet.

*Wavelengths are given in nanometers (nm). There are 10^9 nm to a meter.

†The argon laser produces blue-green coherent light at a number of wavelengths but most of the energy is at wavelengths 488 nm and 514 nm.

From Abdelmalak B, Doyle DJ, eds. *Anesthesia for Otolaryngologic Surgery*. Cambridge, UK: Cambridge University Press; 2012.

One special concern is that regular ETTs can ignite from a laser beam. In the past, metallic tapes applied in a spiral manner were sometimes used. Today, however, several special-purpose ETTs are available for this purpose (Table 70.2).

TABLE 70.2 Some Types of Laser Endotracheal Tubes in Clinical Use

Name	Description	Intended Use
Laser-Flex	Airtight stainless steel corrugated spiral with a PVC Murphy eye tip and double cuffs. More information is available at http://www.cardinal.com/us/en/distributedproducts/ASP/43168-145.asp.	CO_2 or KTP lasers
Laser-Shield II	Silicone rubber tube wrapped with aluminum and wrapped over with Teflon. More information at http://assets.medtronic.com/ent/flipbook-us/files/assets/basic-html/index.html#190	CO_2 or KTP lasers
Lasertubus	Soft white rubber, reinforced with corrugated copper foil and an absorbent sponge; double cuffed. More information at http://www.myrusch.com/images/rusch/docs/A20C.pdf	CO_2 or KTP lasers
Sheridan Laser-Trach	Red rubber design with embossed copper foil and outer covering designed to reduce damage to mucosal surfaces and vocal cords. More information at http://www.teleflex.com/en/usa/productAreas/anesthesia/documents/Sheridan-ET-Tube-Guide.pdf	CO_2 or KTP lasers

CO_2, Carbon dioxide; *KTP*, potassium titanyl phosphate; *PVC*, polyvinyl chloride.

The choice of anesthetic technique depends on the clinical circumstances. TIVA techniques for laser ENT surgery are particularly popular and are essential when patients are unintubated and jet ventilation is used. When patients are intubated, a potent inhalational agent such as sevoflurane is often used, although frequently an infusion of remifentanil is used as an anesthetic adjunct in such cases (typical rate: 0.05-0.1 µg/kg/min). (Remifentanil, with its vagomimetic effect, is especially useful to limit the heart rate in the face of intense sympathetic stimulation from the effects of the suspension laryngoscope.) Finally, to reduce the chance of a fire, while lasers are in use nitrous oxide should not be used, and the oxygen concentration should be limited to the lowest concentration necessary to maintain acceptable arterial oxygen saturation levels.

Airway management is often a challenge in laser surgery cases, and the surgeon and anesthesiologist must work together to devise a plan. One issue is whether general anesthesia should be preceded by awake intubation because the presence of airway disease may complicate both ventilation and intubation. Another issue is whether the procedure should be performed using general anesthesia with the patient breathing spontaneously, albeit with assistance, as is sometimes desirable when an anterior mediastinal mass is present. Muscle relaxation is often employed to help ensure an immobile surgical field. With the widespread availability of sugammadex, most clinicians are able to use rocuronium as a relaxant, followed by a "sugammadex rescue" should the airway become unmanageable following relaxant administration. Many clinicians, however, simply intubate the patient awake whenever issues of this kind arise.

In some cases, the entire surgical procedure is done without intubation. The advantages of this approach are a decreased risk of fire (no ETT to ignite) and improved access to airway structures. Disadvantages include the risk of aspiration with an unprotected airway and potential difficulties in ventilating the patient. Typically in such cases, an anterior commissure laryngoscope or similar device is used in conjunction with TIVA and jet ventilation. In other cases, the laryngoscope is used in conjunction with a small-diameter ETT (e.g., MLT size 5.0), and the procedure is performed while the patient has brief periods of apnea in conjunction with intermittent removal of the ETT to allow unimpaired access to the glottic structures.

Laser vaporization of tissue, especially from CO_2 lasers, often results in a plume of smoke that can be hazardous. The use of a smoke evacuator at the surgical site along with protective masks that filter out particulate material is often advised, especially when virus particles are present in the vaporized tissue.

Extubation of the trachea in these cases can be challenging. Some patients benefit from the administration of intravenous dexamethasone to reduce edema. Stridor is sometimes encountered after extubation; although this condition may require reintubation, one can sometimes avoid this by the use of inhaled racemic epinephrine or the use of Heliox, a mixture of helium (typically 70%) and oxygen. Extubation over a tube exchanger can be helpful when the need for reintubation is a concern and is expected to be challenging.

Even when the tracheas of patients are extubated conservatively following laser surgery, airway problems can arise later. In cases of immediate respiratory distress following laser procedures, consider the following possibilities: tissue edema (e.g., after Nd:YAG laser use), residual muscle relaxant or anesthetic effects, airway secretions, pneumothorax, bleeding, and pneumomediastinum.

Phonosurgery

Phonosurgery is surgery conducted to improve a patient's voice.[181-185] In many cases the patient's voice has been damaged as a result of unilateral vocal cord paralysis. One common operation used in this setting is medialization of the paralyzed vocal cord (laryngoplasty) so that the normal vocal cord can make contact with the paralyzed side. This procedure is done using local anesthesia with minimal sedation (e.g., 20 mg propofol administered just before the injection of the local anesthetic) because the patient needs to phonate on request. Continuous intraoperative imaging of the vocal cords, especially during phonation, is carried out to achieve the repair. An infusion of dexmedetomidine is sometimes used.

Head and Neck Flap Reconstructive Surgery

Tissue transfer in the form of pedicle flap or a microvascular free flap is commonly employed to reconstruct defects created following tumor surgery.[186-188] Potential advantages of such flaps include the avoidance of staged procedures, improved wound healing, superior cosmetic results, and improved tolerance for postoperative radiation therapy. For optimal anesthetic care, anesthesiologists must have a clear understanding of these procedures and their implications for anesthetic management.

A *pedicle flap* is one in which the flap vessels are transferred intact with the rotated flap. If the flap is moved from a distant "donor" site and the flap vessels are reanastomosed to the recipient site vessels, then the tissue is termed a *microvascular free flap.* Examples of myocutaneous pedicled flaps are the pectoralis major flap and the latissimus flap used (for instance) to cover the carotid artery after the point where it is sacrificed and reconstructed using a vein graft. In contrast to pedicle flaps, free flaps provide the surgeon with more options for donor sites. Frequently, separate surgical teams for the donor and recipient sites are employed. Surgery in relation to free flaps can be elective, or it may be performed on an emergency basis to rescue an ischemic flap. Elective procedures tend to be long-duration operations conducted using general anesthesia. An arterial cannula is generally used, although special care must be taken to ensure that the arterial cannula and any additional intravenous catheters are not inadvertently placed at a site where tissue harvesting is planned (e.g., radial forearm flap). Central lines are not usually placed, in part because information about volume status can usually be better achieved using less invasive means such as systolic blood pressure variability. Many of these procedures begin with a tracheostomy and end with the patient being cared for in an ICU while intubated and ventilated. Intraoperative and postoperative flap monitoring is achieved clinically (examination for color, turgor, edema, and capillary refill), as well as by using technical means of blood flow assessment, such as Doppler ultrasound.

Intravenous crystalloids and colloids are administered liberally but cautiously to prevent hypovolemia and hypotension that could lead to ischemic flap failure. Conversely, excessive fluid leads to detrimental edema formation within the flap. The use of vasopressors such as phenylephrine or norepinephrine is generally discouraged during free flap procedures because these drugs may contribute to graft ischemia as a result of vasoconstriction.

Stridor and Heliox

Stridor is noisy inspiration resulting from turbulent gas flow in the upper airway. Stridor should always command clinical attention because it is almost always the result of airway obstruction.[189-194] The first issue of clinical concern in the setting of stridor is whether intubation is immediately necessary. If intubation can be delayed for a period of time, a number of potential options can be considered, depending on the severity of the situation and other clinical details. These options include the following: expectant management with full monitoring, 100% oxygen by facemask, and positioning the head of the bed for optimum conditions (e.g., 45-90 degrees); use of nebulized racemic epinephrine (e.g., 0.5-0.75 mL 2.25% solution in 2.5 mL normal saline) and dexamethasone ([Decadron] 4-8 mg intravenously every 8-12 hours) when airway edema may be the cause of the stridor; and use of Heliox (70% helium, 30% oxygen). Dexamethasone can take several hours to take full effect, and nebulized cocaine in a dose not exceeding 3 mg/kg can be used instead of racemic epinephrine. Finally, whenever possible, immediate attempts should be made to establish the cause of the stridor (e.g., foreign body, vocal cord edema, arytenoid cartilage dislocation, tracheal compression by tumor).

Frequently, stridor occurring after extubation is the result of laryngeal edema, and it may be more problematic in children because of their small airway size. Be aware that as laryngeal edema progresses, diminished stridor may reflect impending total airway obstruction. The specific cause of laryngeal edema can often be established with fiberoptic nasopharyngeal examination, and causes are often classified as supraglottic or subglottic. Supraglottic edema most commonly follows surgical instrumentation, impaired venous drainage, eclampsia or preeclampsia, hematoma formation, or excessive fluid administration. Subglottic edema may result from traumatic intubation attempts, bucking on the ETT, prolonged intubation, tight-fitting tubes, or excessive cuff pressures.

The manner in which Heliox helps relieve airway obstruction is worthy of note. Some airway-obstructing conditions may be thought of as breathing through an orifice, involving flow through a tube whose length is smaller than its radius. Gas flow through an orifice is always somewhat

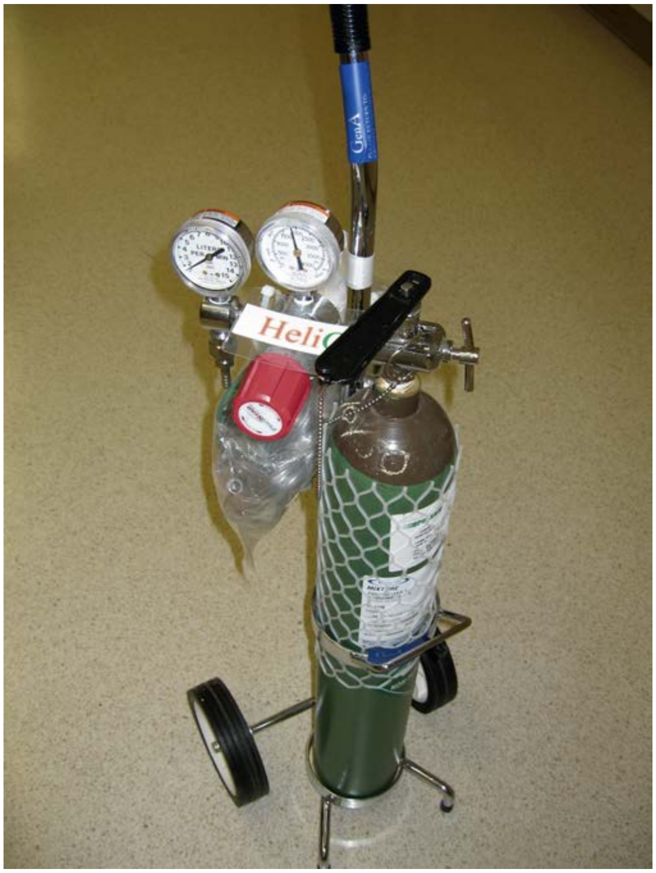

Fig. 70.13 An E-size tank of Heliox, with an attached nonrebreathing facemask in a plastic bag. In this case, the mixture is 70% helium and 30% oxygen, although other mixtures are available. This gas mixture is usually given using a nonrebreathing facemask with a gas flow of 10 L/min as a temporizing measure in stridulous individuals.

turbulent. Under such conditions, the approximate flow across the orifice varies inversely with the square root of the gas *density*. This is in contrast to laminar flow conditions, in which gas flow varies inversely with gas *viscosity*. Although the viscosity values for helium and oxygen are similar, their densities are very different. For example, the density for air and oxygen at 20°C is 1.293 and 1.429 g/L, respectively. However, the density of helium at that temperature is only 0.178 g/L. Clinically, Heliox is usually administered from an E-size cylinder through a nonrebreathing facemask starting at a flow of 10 L/min (Fig. 70.13). When the usual 30% oxygen concentration is too low, one trick is to titrate in additional oxygen by nasal cannula. In summary, a setup to administer Heliox should be readily available in every ENT operating room suite to assist in the treatment of stridor.

Anesthesia for Face Transplantation

Face transplantation remains a very rare procedure (Fig. 70.14).[195,196] The procedure can be total or partial. The recipient must be able to undergo a very prolonged anesthetic and be free of serious comorbidities. Each procedure is unique with respect to indications, as well as with respect to the nature and the extent of the graft. In the case of the donor, although anesthetic principles similar to conventional organ procurement apply, because of the surgical complexity and time involved, harvesting of the facial graft should ordinarily be performed before harvesting other organs. Although the donor usually has an ETT in place at the time of tissue procurement, a tracheostomy may be performed first to avoid interference with the surgical field. Recipient patients who do not have a tracheostomy may first require awake fiberoptic oral intubation, followed by a tracheostomy. A wire-reinforced ETT is often used. Large-bore catheters are placed to facilitate fluid resuscitation, whereas a central line may be useful to monitor central venous pressure. If a central line is used, however, it must not impinge on the surgical field. Blood and fluid management is no different from that during other long surgical procedures involving microvascular free flaps. As with microvascular surgery, pressors such as phenylephrine or norepinephrine, commonly used to treat hypotension, are discouraged because of the risk of compromising graft

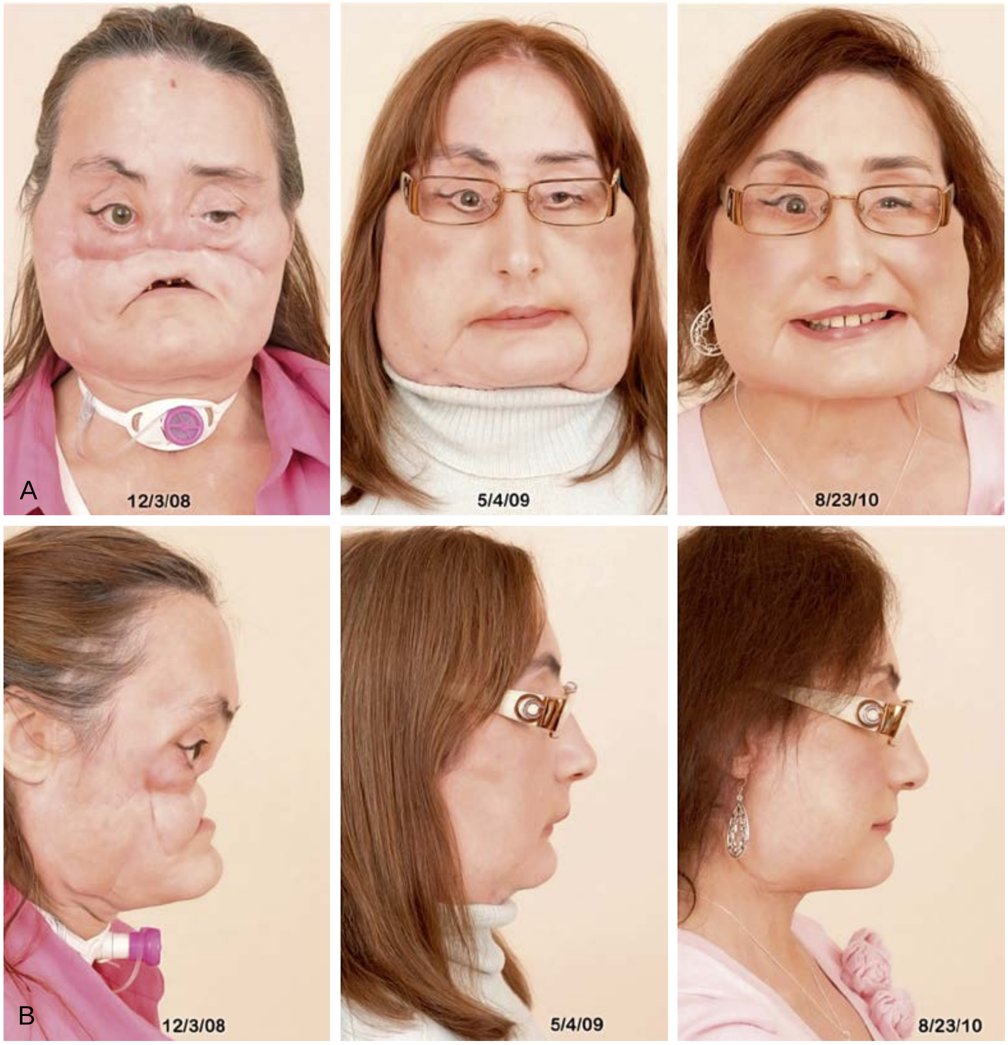

Fig. 70.14 Ms. Connie Culp before (A) and after (B) the two stages of her face transplant at Cleveland Clinic. Stage 1 was carried out in December 2008 (lead surgeon: Dr. Maria Siemionow). (Images courtesy the Cleveland Clinic, Cleveland, Ohio.)

perfusion. Finally, there may be periods when muscle relaxation must be avoided to allow nerve identification using electrical stimulation.

Acknowledgment

This chapter is a consolidation of two chapters in the 8th edition, Chapter 85 Anesthesia for Ear, Nose, and Throat Surgery by D. John Doyle and Chapter 88 Anesthesia for Laser Surgery by Vicki E. Modest and Paul H. Alfille. Their chapters have served as the foundation for the current chapter. The editors and publisher would like to thank the authors for their contributions to the prior edition of this work.

Anesthesia for Robotic Surgery

DAN B. ELLIS and MEREDITH A. ALBRECHT

KEY POINTS:

- Robotic surgery has witnessed explosive growth. Currently (2018) more than 3 million procedures have been performed using the da Vinci system worldwide.[1]
- Robotic surgery is not true autonomous surgery but instead the robot is used as mechanical “helping hands” aiding skilled surgeons.
- By creating three-dimensional views, allowing increased movement of laparoscopic instruments within a patient’s body, and allowing precise movements, robotic surgery can enhance a surgeon’s ability to visualize pathologies and to perform complex procedures.
- Given the size of robotic equipment and the need for specific patient position during procedures, robotic surgery may present unique challenges for anesthesia providers.
- To facilitate surgical exposure, robotic surgery often requires insufflation of a body cavity with carbon dioxide. Insufflation and resorption of carbon dioxide can lead to a variety of physiologic changes.
- Robotic surgery has been successfully used to care for patients receiving urologic, gynecologic, colorectal, hepatobiliary, otolaryngologic, cardiac, and thoracic procedures.

What Is a Robot?

According to Merriam-Webster, a robot is “a machine that resembles a living creature in being capable of moving independently (as by walking or rolling on wheels) and performing complex actions (such as grasping and moving objects).” Developed in the 1980s by the National Aeronautics and Space Administration (NASA), a robot is a remotely controlled device that allows tasks to be performed in spaces removed from human presence. Eventually, robots began to perform tasks aboard NASA spaceships. While the initial concept of robotic science was useful in space exploration, the U.S. government began looking for other applications of the technology.

The US Department of Defense (DOD) began working to apply the robots that were useful in space to the battlefield. Recognizing that an inordinate number of American soldiers died on the battlefield from hemorrhage or untreated surgical wounds, the DOD looked to use these technologies in surgical theaters. With the goal of having a surgeon remotely operate on patients in difficult-to-reach locations, the military invested in developing remotely controlled articulating arms that could perform surgical procedures.

At the same time, the world’s first laparoscopic cholecystectomy was performed in France. This procedure forever altered the course of traditional surgery, and the minimally invasive era of surgical procedures began.

Over the next decade, several companies developed a variety of medical robots and rapidly advanced the science. The first such device appeared in the early 1990s, when an instrument was created to pulverize bone and create space for hip prosthesis during orthopedic surgery.

As work progressed on creating devices to perform procedures, work also continued on allowing remote control of devices. In the mid-1990s, voice recognition software was used to control a laparoscope’s position and to aid in organ retraction during traditional laparoscopic surgery. This device, called Automated Endoscopic System for Optimal Positioning (AESOP), is still available today (Fig. 71.1). In many ways, this device was the precursor to the smart devices in our homes and on our persons.

Arguably the greatest advancement in robotic surgery occurred in 1991 when a master-slave version of a robot was developed. This device allowed a surgeon to sit apart from his/her patient and remotely control articulating arms. Two similar devices, the da Vinci Robotic Surgical System, and the ZEUS Surgical System, appeared on the market at similar times. The parent company of da Vinci, Intuitive Surgical, acquired the intellectual property rights to the ZEUS system and discontinued the product. As a result, only the da Vinci Robotic Surgical System is available for use today (Fig. 71.2).

Eventually, high-definition, three-dimensional cameras were added to robots, allowing surgeons to explore a patient’s anatomy and access traditionally difficult-to-reach surgical sites from a console located next to the operating table. While several robotic companies have developed products, at the moment, only two remain: AESOP and da Vinci.

The da Vinci robot has four components (Figs. 71.2 and 71.3):

1. Surgeon console (Figs. 71.4 to 71.6)
2. EndoWrist instruments (Figs. 71.7 and 71.8)
3. Optical vision cart
4. Patient cart with four movable arms (Fig. 71.9)

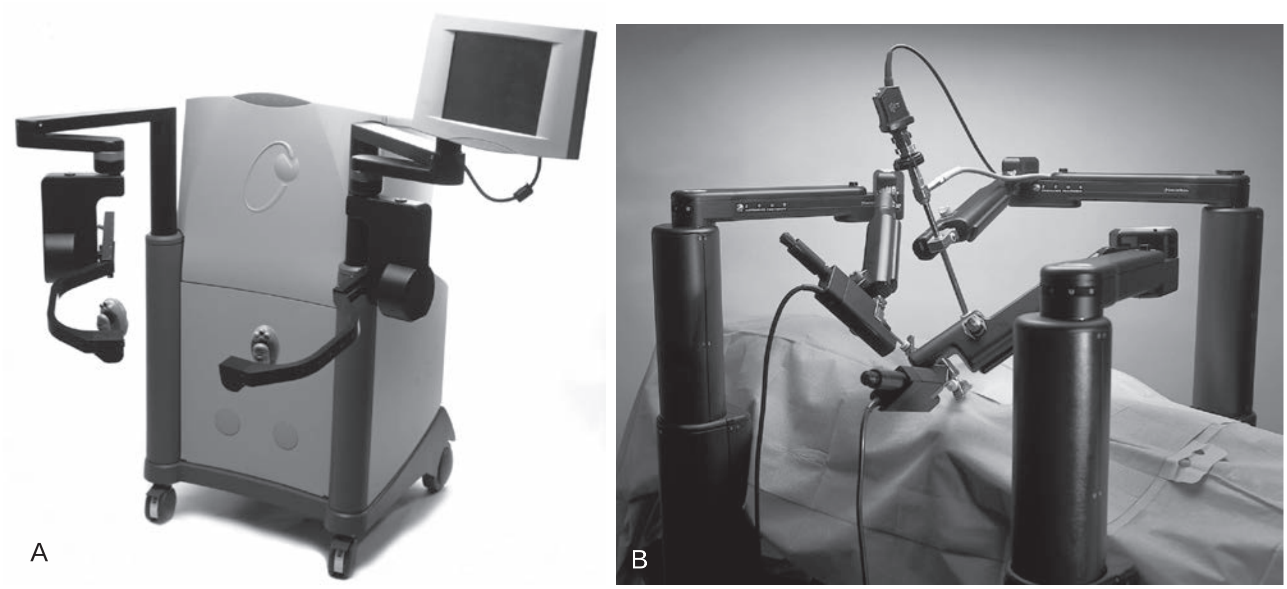

Fig. 71.1 (A) The console of the ZEUS robotic telemanipulation system consists of a video monitor and two instrument handles that translate the surgeon's hand motions into an electric signal that moves the robotic instruments. (B) Two table-mounted Automated Endoscopic System for Optimal Positioning (AESOP) arms hold instruments, and a third arm controls the camera. (Courtesy Computer Motion, Sunnyvale, CA, USA.)

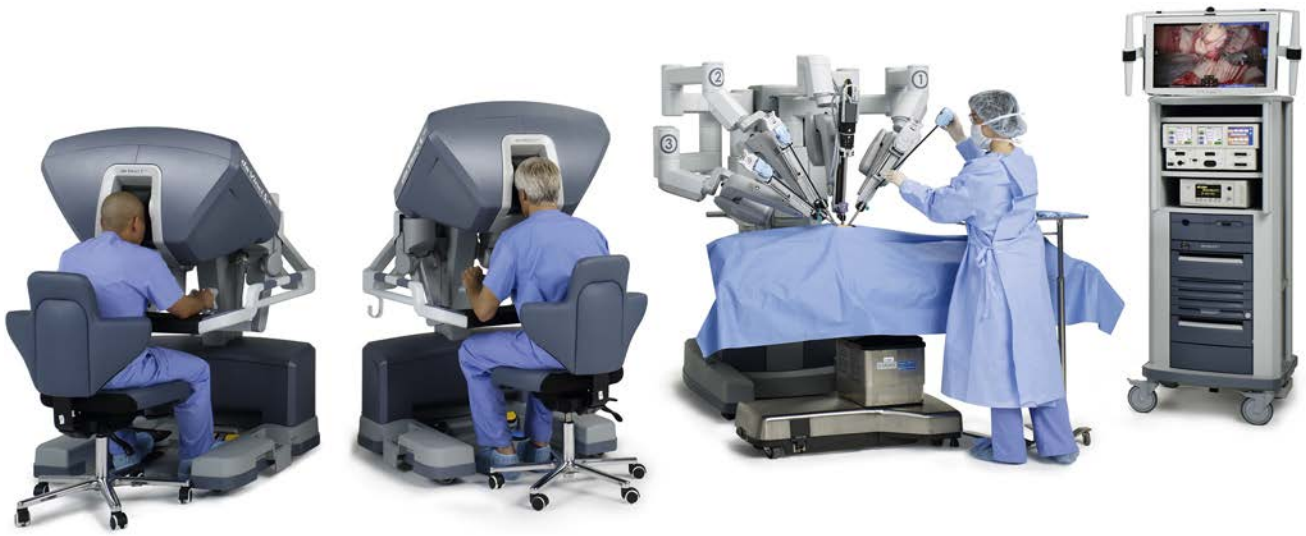

Fig. 71.2 The da Vinci Robotic Surgical System: two surgical consoles, patient-side cart with four mounted surgical arms, and an optical tower. (Courtesy Intuitive Surgical, Sunnyvale, CA, USA.)

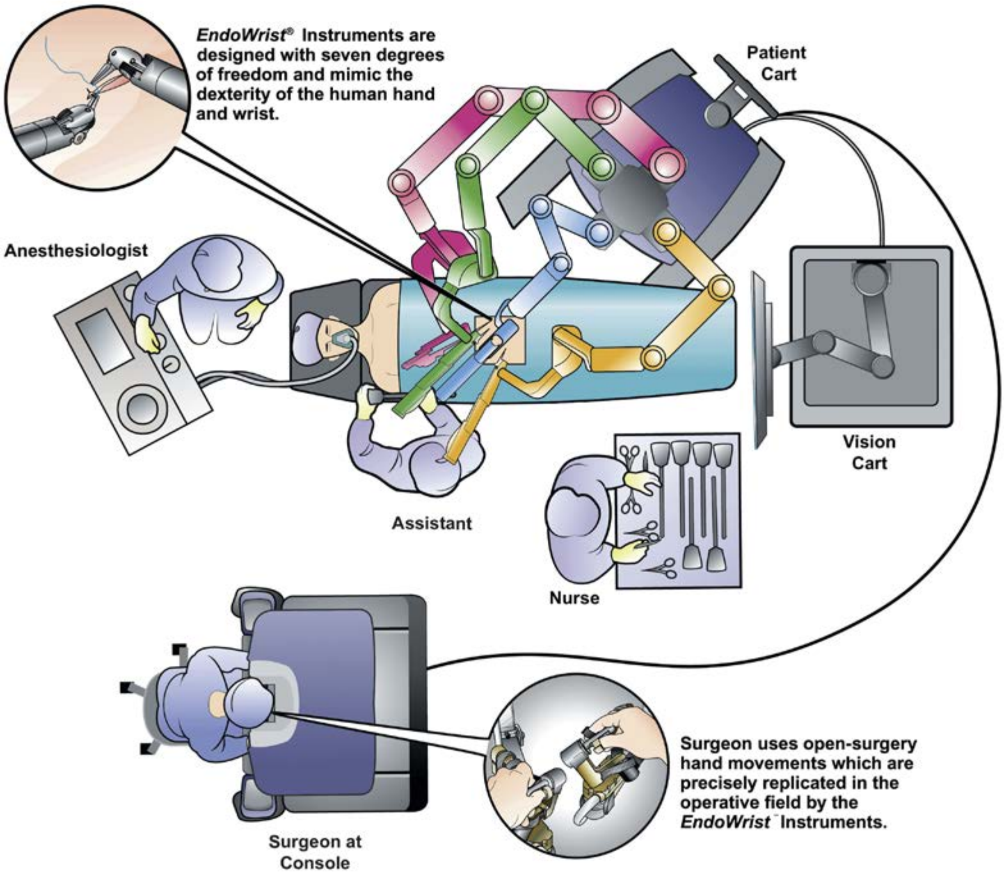
The surgeon sits at the surgeon console (see Figs. 71.4 and 71.5) and remotely controls the EndoWrist instruments that are attached to the patient cart. Anesthesia personnel, surgical assistants, and circulating nursing staff may see the procedure in real time via the screen on the optical vision cart (see Fig. 71.2).

During an operation, the surgeon views two high-definition monitors that mimic a binocular or microscope. This two-monitor view creates three-dimensional images. The surgeon's arms rest on the master controls, and his/her fingers manipulate the levers that control EndoWrist articulation. Foot pedals control electrocautery, movement of the robotic camera, and disengagement of robotic instruments. To facilitate collaboration and training, the da Vinci machine will often have two consoles allowing two surgeons to participate in the patient's care.

Why Is the Robot Preferred?

The robot is preferred to open procedures because it allows a minimally invasive approach to surgical pathologies. Less tissue manipulation leads to fewer adhesions and potentially faster recovery from surgery. Fewer wound complications, including infections and incisional hernias, and shorter hospitalizations make robotic surgery attractive when compared to other minimally invasive or open techniques.[2] Further, the robotic approach to surgical procedures allows discrete movements that are helpful in microsurgical dissection and re-attachment of tissues. In comparison with human arms, robotic arms permit seven degrees of free movement. These movements can be categorized into: gross arm movement by the da Vinci robot, fine movements by the articulating arms,



EndoWrist® Instruments are designed with seven degrees of freedom and mimic the dexterity of the human hand and wrist.

and surgical actions performed by the articulating arms (Table 71.1, Figs. 71.7 and 71.8).

These articulating arms are not limited by constraints associated with human wrist joints. Additionally, the robot allows for larger, more coarse movements to be miniaturized in the operating field. For example, moving the controls by 5 mm may move the articulating arms by only 1 mm. This miniaturization permits more fine control. Furthermore, robotic software can reduce or eliminate hand tremors, thereby improving the safety and precision of surgery.

When Is the Robot Used?

The robot is used in hysterectomy, prostatectomy, nephrectomy, cardiac surgery, colectomy, general laparoscopic, thoracoscopic, and transoral otolaryngologic procedures. Although most procedures performed using the da Vinci robot are urologic (prostatectomy) and gynecologic (hysterectomy), a wide range of new applications are being discovered.

Essentially, robotic surgery is helpful whenever microsurgery is necessary and the target organ is difficult to reach. It is especially valuable if its usage converts what is traditionally an open procedure to a minimally invasive procedure.

Future Applications of Robotic Surgery

As imaging modalities and artificial intelligence are applied to robotic surgery, the field will evolve. It is probable that nonrigid, flexible articulating arms of progressively smaller size will ultimately replace the current, rigid articulating arms. "Snake-like" articulating arms will facilitate fewer and smaller incisions to be made in a patient and allow less invasive, perhaps even scar-free, surgery to be performed. Finally, as artificial intelligence evolves, it is possible that semi-autonomous robotic surgery will develop with computer algorithms guiding surgical instruments.

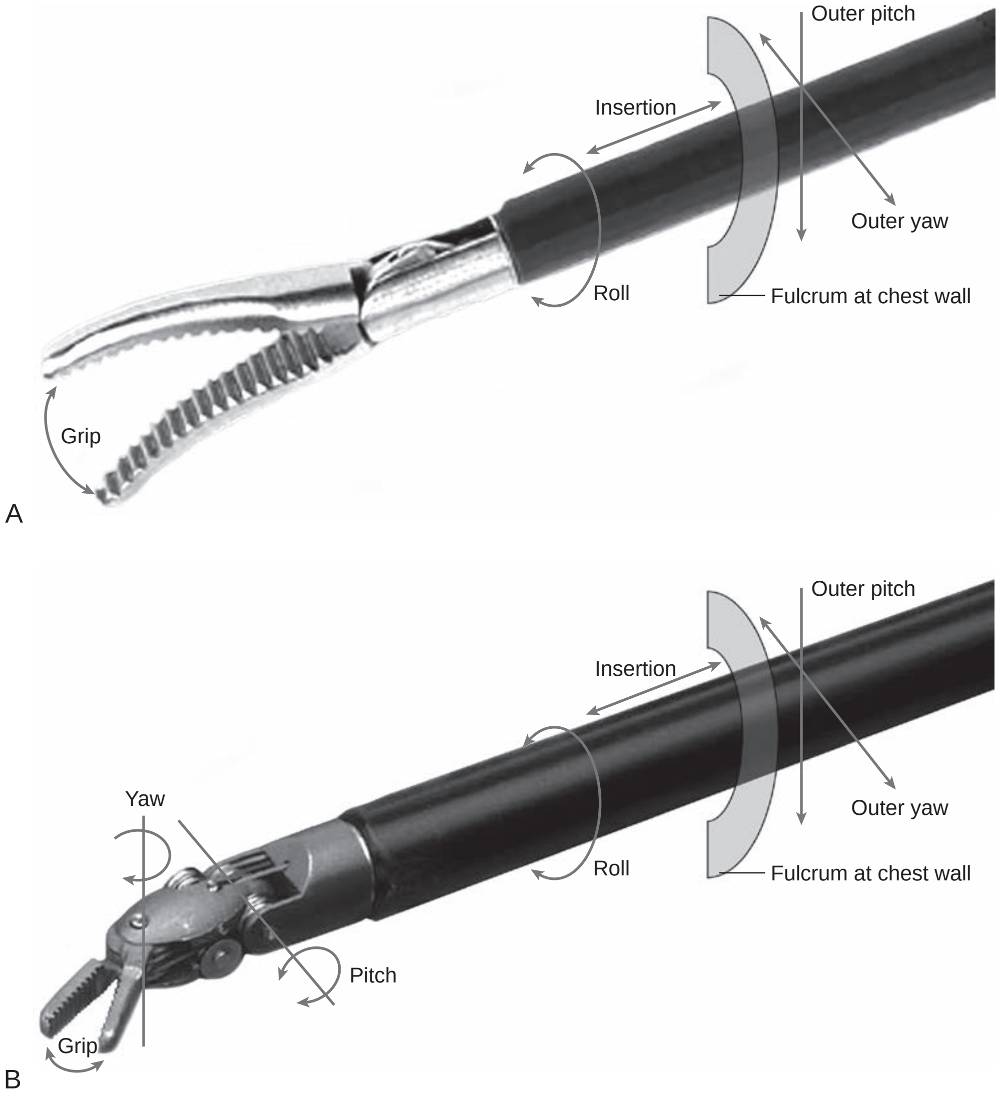

Fig. 71.7 Degrees of freedom (DOF) in motion. (A) Conventional laparoscopic instruments have only four DOF and grip. Insertion (i.e., movement in the *z*-axis), roll, and movement along the *x*- and *y*-axes outside the body relative to a fulcrum point constitute the four DOF. (B) Depiction of the EndoWrist instrument with two added intracorporeal joints, producing seven DOF. (Copyright 1999 Intuitive Surgical, Sunnyvale, CA, USA.)

ROBOTICALLY ASSISTED INTUBATION

There have been reports of successful robotic intubations. The Kepler Intubation System (KIS), developed by Thomas Hemmerling, has been shown to intubate mannequins successfully by an operator who has either a direct or indirect view of the patient. KIS is a low-cost system consisting of a joystick, a robot arm, the Pentax videolaryngoscope, and a software control. The intubations occurred within 40 to 60 seconds with a 100% success rate on the first attempt. This system also allowed for semiautomated (a computer system replayed prior operator driven movement sequences) intubations that occurred in less than 45 seconds and had a 100% success rate.[3] The system has also been used on 12 patients and was successful with a first-pass intubation in 11 of the 12 patients (1 was unable to be completed due to fogging of the equipment). The intubations were done in approximately 93 seconds.[4,5] It remains to be seen if a robot intubation system will have widespread use. However, it may have applications in settings where it would be difficult to transport a trained anesthesia provider to the location, such as deep space exploration.

ROBOTIC SURGERY PHYSIOLOGY

Robotic surgery causes a number of physiologic changes. Positioning, insufflation with carbon dioxide (CO_2) to allow visualization of the surgical field, and physiologic changes associated with increasing intracompartmental pressure (i.e., abdominal, thoracic, or oral) are all seen with robotic surgery. Therefore, it is imperative that anesthesia providers are aware of these perturbations so that appropriate compensatory plans may be created.

Insufflation With CO_2

Except for otolaryngological procedures, inert gas must be insufflated into a patient's body to visualize the surgical field. CO_2 is the inert gas of choice because it has a high diffusion coefficient and the risk of a gas emboli is minimized since CO_2 is easily excreted from the body through the respiratory

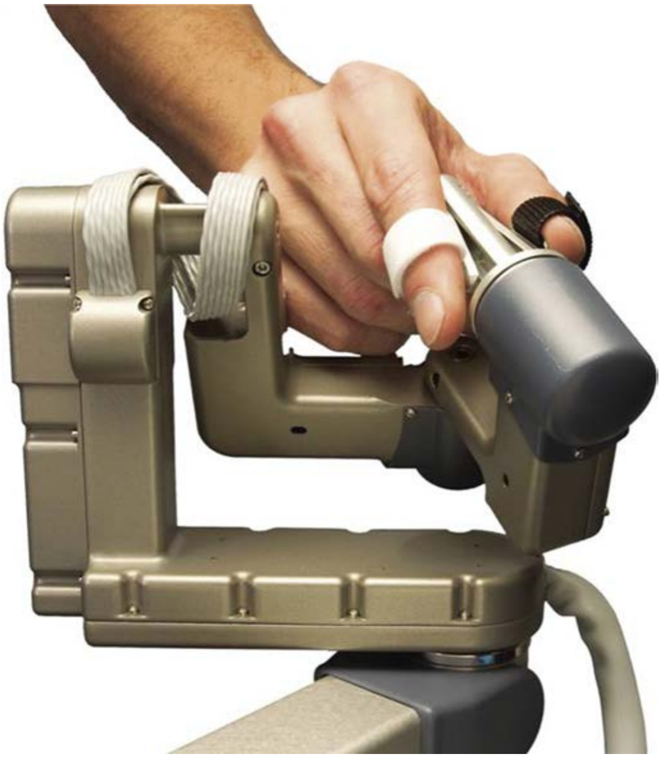

Fig. 71.8 The EndoWrist instrument of the da Vinci Robotic Surgical System mimics the natural kinematics of the surgeon's hand and wrist. This design allows more degrees of freedom. (Courtesy Intuitive Surgical, Sunnyvale, CA, USA.)

Up and down	Pitch (up and down)	
Side-to-side	Rotation and roll	

system.[6] As CO_2 is insufflated into the abdomen, surgeons exercise caution to keep intraabdominal pressures below 20 cm of water. By minimizing intraperitoneal pressure, the vagal stimulation from elevated intraabdominal pressure is minimized. However, if the patient has a particularly pronounced resting vagal tone or a significant vagal response to peritoneal insufflation, pharmacologic intervention by the anesthesia provider or reduction of pneumoperitoneum may be necessary.

Insufflating the surgical site with CO_2 also may lead to sudden increases in CO_2 in the blood stream because it is absorbed from lymphatic and venous plexi.[7] As a result, increasing minute ventilation is necessary to maintain normocarbia and to keep the patient in homeostasis.

Another potential untoward effect of CO_2 insufflation is gas embolism.[7] Although rare, a gas embolus may have catastrophic effects on the cardiopulmonary system if the embolus becomes lodged in the pulmonary system. Additionally, if a patient has an atrioseptal or ventriculoseptal defect, he or she may develop a gas embolus in the cerebrovasculature with potentially devastating complications.

A more common and less devastating complication of gas insufflation and increased intraperitoneal pressure is atelectasis. This is exacerbated by the effects of insufflation on diaphragmatic excursion.[8] CO_2 insufflation may lead to pneumomediastinum or subcutaneous emphysema (incidence of 0.43%-2.3%). Although this finding typically has no clinical consequences, it may be associated with prolonged CO_2 excretion postoperatively causing hypercarbia and acidosis. Also, there have been reported cases of pneumothorax caused by extension of insufflated gas through diaphragmatic congenital channels into pleural cavities (incidence of 0.03%). An increased incidence is associated with an increased number and size of trocars, longer surgical time, higher gas flow rate, intensified gas pressure, loose trocars, and difficult trocar placement. Due to a number of factors, such as lack of external visualization and haptic feedback during robotic surgery, there is an increased incidence of gas extravasation.[9]

Pulmonary Vasoconstriction

Pulmonary vasoconstriction results from insufflation due to:

1. CO_2 absorption, and
2. physical compression of the lungs.

CO_2 absorption results in hypercarbia and acidosis. The pulmonary system's response to hypercarbia is vasoconstriction, in order to preserve gas exchange by preferentially shunting blood away from less ventilated portions of the lungs. Therefore, carbon dioxide insufflation has a vasoconstricting effect on the pulmonary vasculature.

In addition, during robotic surgery, pneumoperitoneum results in compression atelectasis as the intrathoracic pressure competes with elevated intraperitoneal pressures resulting in lung tissue compression. This process is worsened by Trendelenburg positioning. Nasogastric or orogastric tubes may facilitate gastric decompression and help reduce, albeit not eliminate, increased intraabdominal pressures. As functional residual capacity decreases, patients may experience increased lung collapse and atelectasis. This phenomenon combined with the vasoconstriction due to the CO_2 insufflation increases the ventilation/perfusion mismatch. This mismatch results in decreased oxygenation.

Atelectasis also leads to hypoxic pulmonary vasoconstriction (HPV). HPV is a compensatory mechanism that allows the body to preferentially divert blood from oxygen-poor regions of the lungs to oxygen-rich regions. and improves gas exchange by shunting blood to areas of the lung that are ventilating normally.[7] This effect appears to be caused by mitochondrial sensors inspiring voltage-gated calcium channels to increase the cytosolic calcium, thereby leading to vasoconstriction.

Insufflating the peritoneum also decreases respiratory compliance and elevates airway pressures. This process makes ventilation increasingly difficult and worsens the aforementioned hypercarbia.[10] To improve ventilation it has been recommended to switch mode from volume control ventilation to pressure control ventilation (PCV). However it has been shown in a randomized trial of patients for robot-assisted laparoscopic radical prostatectomy that aside from lower peak airway pressures and improved compliance in the PCV mode, there was no benefit in other parameters, such as: central venous pressure, mean pulmonary arterial pressure, pulmonary capillary wedge pressure, cardiac index, arterial oxygen pressure, mean airway pressure, physiological dead space, and intrapulmonary shunt fraction.[11]

Elevated CO_2 levels also shift the oxyhemoglobin dissociation curve to the right via the Haldane effect. This shift in the dissociation curve helps deliver oxygen to the tissues and results in slightly less ischemia than would be expected.[12-14] A potential explanation for this phenomenon is that carbon dioxide inspires the Haldane effect and HPV.

Cerebral Vascular Effects

Increased absorbed CO_2 from insufflation also leads to cerebrovascular dilation. Although CO_2 leads to blood being preferentially shunted away from the pulmonary vasculature, CO_2 in the cerebral circulation leads to cerebral vascular dilation. Anesthesiologists must be mindful of the potential increase in intracranial pressure (ICP) that may arise from elevated CO_2 levels.[15,16] Additionally, a number of robotic procedures require steep Trendelenburg positioning to allow surgical visualization of pelvic structures, which also results in increased ICP. Anesthesiologists must be cognizant of possible increased ICP especially in cases where patients need a ventriculoperitoneal shunt due to baseline increases in ICP.

Systemic Effects of Hypercapnia

Hypercapnia will lead to a respiratory acidosis as CO_2 is combined with water and is metabolized into bicarbonate and hydrogen ions. Since bicarbonate does not effectively buffer the acidosis induced from hypercarbia, a respiratory acidosis occurs.[17,18]

Hypercapnia will augment anesthetic effects. Acute hypercapnia will also result in depressed consciousness when $PaCO_2$ exceeds 80 mm Hg.[19] Increased CO_2 also decreases myocyte contractility and can potentially increase the myocardial susceptibility to arrhythmias.[20]

Patient Positioning. Patient positioning during robotic surgery can present a challenge. By definition, robotic surgery requires remote operation of laparoscopic equipment and surgical instrumentation. Therefore much of the normal feedback between surgeon and patient is altered, as surgeons are removed from their patients and replaced by bulky steel instrumentation. Therefore, patients are at much higher risk of iatrogenic injury than their nonrobotic peers. Also, this separation from the patient, and working from the inside of the surgeon console, makes communication between the operating room team and the surgeon difficult.

To minimize nerve injuries, careful attention must be paid to patient positioning. Given the size of the robot, a patient's arms are tucked at his or her sides and are often inaccessible during an operation. Once a robot has docked, access to the patient is hampered. Therefore, if an anesthesia provider is considering additional intravenous/arterial access, consider placing these lines after induction of the anesthesia and prior to docking of the robot. A best practice is to place at least two intravenous catheters in addition to an extra noninvasive blood pressure cuff with an extra connector and hose prior to docking of the robot. This allows more flexibility with intraoperative monitoring of the patient, even during periods of very minimal access.

Further, the type of surgical procedure creates unique positioning considerations. If surgeons are operating on pelvic organs, patients require steep Trendelenburg positioning. Alternatively, if patients are receiving abdominal wall surgery, then the supine positioning is often required.

If a patient is to be placed in steep Trendelenburg position, then the best practice is to tuck a patient's arms at his or her sides to minimize brachial plexopathy from hyperextension of the arms. In addition to minimizing the risk of brachial plexus injury, a patient's arms may be tucked at his or her sides to also allow the robot access to the patient. Foam padding and silicone pads are employed to protect vulnerable nerves. If the patient's arms are not tucked at his or her sides, then care must be paid to making sure brachial plexus injuries do not occur from hyperextension of the arms. Additional padding may be necessary to protect a patient's face, head, and neck from robotic arm movements, and vigilance by an anesthesia team is mandatory.

Given the need for patient immobility during a procedure, continuous neuromuscular blockade is paramount as patient movement resulting from intense surgical stimulation in the setting of inadequate anesthesia or insufficient neuromuscular blockade may lead to significant patient injury. To allow for titratable paralysis during robotic cases, many clinicians infuse neuromuscular blocking agents. As a result, continual monitoring of neuromuscular blockade is imperative. Many anesthesia providers place *multiple* intravenous lines so that boluses of medications and fluids may be given through one line while infusions of vasoactive or neuromuscular blocking agents may be given through another.

Please note that the robot arms and the patient's operating room table may not move together. Therefore, once the robot is docked and the robot arms are inside the patient, it is paramount to avoid dyssynchronous movement of the operating room table to avoid tearing injuries of tissue inside the patient.

Physiologic Changes Associated With Patient Positioning

CARDIOVASCULAR EFFECTS

Robotic urologic and gynecologic procedures require steep Trendelenburg positioning to facilitate surgical exposure. When patients are in a steep "head-down" position, blood is funneled from the lower extremities to the right atrium, thereby increasing pre-load. Studies demonstrate a variety of conclusions with respect to the effect of Trendelenburg position on cardiac index and output.[21-24] Patient comorbidities, anesthetized state, and preoperative medications may potentially alter the cardiac output changes induced by Trendelenburg positioning. In general, healthier patients with a robust cardiovascular systems are better able to adjust for hemodynamic changes and tend to have unaltered cardiac output. Also, increases in cardiac output are typically seen only when patients are euvolemic.[25,26]

INTRAOCULAR EFFECTS

Intraocular pressure increases with progressively steeper Trendelenburg positioning. Additionally, longer procedures tend to correlate with greater increases in intraocular pressure.[28-30] If patients suffer from intraocular pathology, that pathology may be exacerbated by longer surgeries and steep Trendelenburg positioning.

URINARY OUTPUT

Urinary output significantly decreases with pneumoperitoneum.[31] However, the decreased urinary output caused by pneumoperitoneum does not appear to negatively impact renal function over time. The decrease in urine output during insufflation does make fluid management more challenging.

After steep Trendelenburg, injuries seen more frequently with robotic surgeries than normal laparoscopic surgeries include urinary retention, infections of the urinary tract, and subcutaneous emphysema.[27]

Types of Robotic Surgery

A large variety of surgeries may be performed using a robot. The most common include urologic procedures such as prostatectomies, cystectomies, and nephrectomies. Also, common gynecologic procedures are hysterectomies, myomectomies, and oophorectomies. Hepatobiliary procedures, colectomies, cholecystectomies, and hernia repairs are also frequently performed.

UROLOGIC PROCEDURES

The first commonly performed robotic urologic procedure occurred in the 1980s with the development of the Unimate Puma robot by Unimation.[32] The Unimate Puma was a machine with six-axes of movement that allowed rapid transurethral resection of prostatic tissue (TURP). This increased efficiency and decreased operative time led to less absorption of irrigation fluid, which resulted in less risk of TURP syndrome.[26,33] As interest in robotic applications to urologic surgery grew, clinicians sought new applications for robotic surgery, including robotic prostatectomies, nephrectomies, and cystectomies, which were being performed by urologists.

Robotic-Assisted Retropubic Prostatectomies

Arguably the most commonly performed robotic urologic procedure is the robotic-assisted retropubic prostatectomy (RAPR). When compared to traditional open prostatectomies or laparoscopic prostatectomies, RAPR appears to have decreased transfusion rates, facilitated faster recovery of urinary continence, and decreased erectile dysfunction. Additionally, RAPR appears to be easier to learn than traditional laparoscopic prostatectomy techniques.

In many ways, the anesthetic plan for a RAPR is like the anesthetic plan for laparoscopic prostatectomy. A standard intravenous induction followed by tracheal intubation is required. Most clinicians advocate for two intravenous lines, as the patient's arms will be tucked at his sides after he is placed in the lithotomy position. A blood bank sample is necessary, as trocars may unexpectedly invade large blood vessels. Neuromuscular blockade is also of extreme importance, as movement by the patient while the robot is docked may lead to significant and serious complications.

As described above, most anesthesia providers recommend placing a second noninvasive blood pressure cuff with a connector and hose on the patient's other arm, in case of difficulty with blood pressure measurement intraoperatively.

To facilitate surgical exposure of deep pelvic organs, patients are often placed in steep Trendelenburg position. As described above, insufflation of the abdomen with steep Trendelenburg positioning leads to an increase in intracranial and intraocular pressures. Since the positioning can result in physical objects hitting the patient's face, it is important to have facial and ocular shields to prevent harm during the case. Several case reports of postoperative blindness and visual field defects have been reported.[34,35] Gastric contents may drain via gravity onto the eyes and potentially cause ocular damage. Therefore, many clinicians advocate decompressing the stomach with an orogastric tube. Although the exact mechanism of ocular damage is not completely understood, decompressing the stomach may help minimize the risk of a trocar advancing into the stomach in addition to protecting the patient's eyes. Increased ICP can lead to strokes or hemorrhages in vulnerable populations.

Fluid management is also very important during robot prostatectomies and requires a delicate balance. Too much fluid given prior to the reattachment of the bladder and the urethra is associated with an increased risk of postoperative anastomotic leak.[36] Since the head is the dependent structure during the case, too much fluid is also associated with glottic and periocular edema. However, using fluid management that is too restrictive can be associated with acute tubular necrosis and the possible risk of a compartment syndrome due to hypotension in the legs. The risk of compartment syndrome is probably less than 0.5% and is associated with longer cases, obesity, and poor positioning.[37]

Robotic-Assisted Radical Cystectomy

Cystectomies are traditionally a difficult operation, as fluid shifts, fluid management, and patient comorbidities present unique challenges. Perioperative management of these patients is sufficiently challenging that nearly 1 out of every 4 patients are readmitted to the hospital following radical cystectomy.[38,39] Unfortunately, readmitted patients often remain in the hospital for roughly a week.[39,40]

Since 2003, robotic-assisted radical cystectomies have been performed in operating rooms around the world.[41] While a number of randomized controlled trials exist, there is a heterogeneity in the data, and diverse conclusions have been drawn based on the patients' long-term results.[42-45] Overall, robotic-assisted radical cystectomy appears to have lower blood loss when compared to open cystectomies. However, this decreased blood loss appears to come at the cost of increased operative times. Of note, there does not appear to be a difference in length of hospital stay[46] or 2-week readmission rates.[47]

Anesthetic considerations for patients receiving robotic-assisted radical cystectomy mirror the considerations for patients receiving robotic-assisted radical prostatectomy. Steep Trendelenburg, increased ICP, and increased ocular pressure are possible. Additionally, the need for CO_2 insufflation is required for visualization.[48]

Robotic-Assisted Nephrectomy

During the past 10 years, radical nephrectomy has been performed to treat renal cancers and is often viewed as the standard of care for patients with T1 and T2 kidney tumors. This surgery, which may result in a cancer-free state, has been performed using an open or laparoscopic technique. In addition, over the last decade, surgeons have begun turning to robotic assistance to perform these surgeries.[49]

Robotic-assisted surgery, when compared to traditional laparoscopic surgery, may allow enhanced visualization of the surgical field and increased degrees of articulation of the surgical arms. Additionally, several meta-analyses demonstrate similar or slightly improved perioperative outcomes when laparoscopic procedures are compared to robotic procedures.[50,51]

Despite many literature reviews and meta-analyses that compare laparoscopic and robotic surgery, there are very few prospective studies comparing perioperative complications and surgical costs. However, there are documented increases in costs and operative times associated with robotic nephrectomies compared to a traditional laparoscopic approach.[49]

GYNECOLOGIC SURGERY

Since 1999, robotic surgery has been used in gynecologic procedures. Robotic procedures were initially used to perform fallopian tubal re-attachment following permanent sterilization, and are currently being used with hysterectomy, salpingo-oopherectomy, vesicovaginal fistula repair, sacrocolpexy, and ovarian cystectomy.[52]

Robotic-Assisted Hysterectomy

After the first gynecological robot-assisted surgery, robotic assistance was quickly applied to hysterectomies, the second most common surgical procedure performed in the United States.[53]

However, despite the large number of patients receiving robotic hysterectomies, it is unclear whether robotics is superior to traditional laparoscopic approaches.[54]

Robotic surgery for endometrial cancer resection does appear to require more surgical operating time, particularly as surgical teams work to become more comfortable with the procedure[55]; proficiency performing the surgery, as approximated by surgical time, appears to improve after 20 to 30 cases.[56] There has been increased concern about the utilization of the robot during endometrial cancer resection surgery since the outcomes appear similar to laparoscopic hysterectomy, but the cost and operative times are greater.[53,57] The American College of Obstetricians and Gynecologists (ACOG) continues to recommend vaginal hysterectomy as the preferred approach for benign disease, where feasible, due to its lower complication rate and faster recovery time. ACOG states that robotic surgery needs to be better studied to discover if a particular subgroup of patients would be best served by this approach.[53]

Providers have begun performing robotic procedures on morbidly obese patients given the physical surgical demands associated with traditional laparoscopy and the greatly increased morbidity associated with an open abdominal approach. In general, the perioperative outcomes appear to be similar.[58,59] However, the positioning of morbidly obese patients into steep Trendelenburg position can be very challenging. Steep Trendelenburg positioning combined with the pneumoperitoneum necessary to facilitate surgical exposure can create cardiovascular and ventilation challenges. While it is possible that this subgroup of patients (body mass index [BMI] > 40), who would otherwise require an open abdominal approach, could benefit from minimally invasive robot surgery, these cases involve a great number of anesthetic challenges.

Other Gynecological Surgeries

Due to the rather steep learning curve for sacrocolpopexy, robot assistance is believed to facilitate this technically difficult procedure. Randomized, controlled trials have shown similar outcomes with robotic versus laparoscopic surgeries. However, the robotic cases can have increased operative time, postoperative pain, and cost.[53] Myomectomies with robot assistance may allow for more minimally invasive surgeries that would otherwise occur due to fibroid location and high patient BMI.

Robot-assisted surgery for gynecological malignancies has been poorly studied with only retrospective comparisons available. Robot assistance was preferred versus an open approach due to decreased cost, length of stay, and complications. A recent meta-analysis focusing on endometrial cancer concluded that robot versus laparoscopy had a similar duration of surgery but shorter hospital stay, less blood loss, fewer conversions to laparotomy, and overall complications, but a higher cost.[60]

ACOG does not recommend the use of the robot for short-duration and low-complexity surgeries such as tubal ligation, simple ovarian cystectomy, ectopic pregnancy, or bilateral salpingo-oophorectomy.[53]

General Surgery

Colectomy. In 1997, general surgeons in Belgium applied robotic techniques to their patients when the first robotic-assisted laparoscopic cholecystectomy was performed.[52]

However, despite many peer-reviewed studies, a recent meta-analysis did not find significant differences between laparoscopic and robotic colectomy surgeries. This lack of difference is perhaps in large part because of the low number of patients in these studies. Additionally, significant heterogeneity existed in the studies, which might have obscured any results.[61]

In a quality improvement analysis, robotic colectomies were associated with statistically significant increases in operative costs when compared to traditional laparoscopic techniques and longer operative times.[62] However, this economic argument may be tempered by a potentially decreased length of stay, as evidenced by a retrospective review of a National Surgical Quality Improvement Program database of 17,000 colectomies.[24]

Cholecystectomy. Another application of robotic surgery is in robotic-assisted cholecystectomy. In this procedure, a single incision is performed, and robotic arms are introduced into the patient's body. This approach is a contrast to the traditional laparoscopic cholecystectomy that requires multiple incisions.[63]

Patients are gravitating towards single-port robotic cholecystectomy procedures for decreased surgical scarring. The daVinci robot has been successfully used in Europe since 2011 before being brought to the United States.[64] Traditional thinking viewed robotic-assisted cholecystectomy as excessively expensive and not warranting a shift away from laparoscopic cholecystectomy,[65] as a recent meta-analysis showed increased operative times for robotic versus laparoscopic cholecystectomy. However, much of this time occurs in the pre-incision phase of the operation.[63]

Additionally, robotic-assisted cholecystectomy is associated with a significantly higher risk of incisional hernia[64] as the incisional hernia rate is approximated to be between 7% and 20%.[66,67] This increased hernia rate may require additional operations and therefore will increase overall healthcare costs.

Hepatobiliary. The liver's unique location deep in the abdominal cavity and its abundant blood supply has slowed surgeons from aggressively adopting and implementing laparoscopic techniques.[68]

Hepatic surgery was first successfully described in 1954 by Claude Couinaud.[69] Since the initial description, laparoscopic approaches to liver surgery have become more common. Additionally, there does not appear to be a difference in tumor recurrence, tumor spread, or survival for patients who receive laparoscopic hepatectomies.[70] Furthermore, minimally invasive techniques appear to be correlated with decreased blood loss when compared to open procedures.[71]

However, the need for greater articulation of surgical instruments, increased mobility of laparoscopic arms, and enhanced surgical visualization has limited wider adoption of laparoscopic surgery, particularly when compared to open procedures.[72] To address these limitations, hepatobiliary surgeons have begun looking to the da Vinci robot. Experienced surgeons usually do not have difficulty transitioning from the traditional laparoscopic approach to robotic surgery.[73] Additionally, robotic surgery allows three-dimensional imaging of a surgical site.[74]

While robotic surgeries are associated with increased intraoperative costs, overall costs of these robotic procedures may be decreased as they generally are associated with shorter lengths of stay compared to open procedures.[75] Thus, robotic surgery in the management of patients requiring hepatobiliary surgery remains an evolving field.

Otolaryngology

There are over half a million cases of head-and-neck cancers in the world.[76]

As otolaryngologists modernize their approach to both benign and malignant pathologies, they have looked to robotic-assisted approaches to replace larger and more invasive neck dissections that were needed to remove oral cancers.

TONSILLECTOMY

Tonsillectomies are one of the most commonly performed procedures in the United States. Although the practice of routinely removing tonsils in childhood has been replaced by more conservative medical management, tonsillectomies are still performed for refractory tonsillitis. As a result, patient demographics are shifting, and patients are presenting later in life with comorbidities not often seen in childhood. Surgeons are looking to innovate and find modern approaches to removing tonsils and adenoid tissues. The robotic articulating arms allow a more minimally invasive approach to resecting the tissue.[77-79]

HEAD AND NECK DISSECTION

Robotic surgery was first applied to oral and maxillofacial surgery in 1994 by Kavanagh,[80] and has rapidly expanded. Now, robotic surgery incorporates the resection of lesions from the base of the tongue, pharynx, piriform sinus, and nasopharynx.[81] Adoption of this technology has even spread to encompass transaxillary thyroid and parathyroid resection as well as uvulopalatopharyngoplasty.[82]

Even though robotic technologies have existed for quite some time, head and neck surgeons in the United States did not immediately adopt them. In fact, for many years, robotic procedures were not approved by the U.S. Food and Drug Administration (FDA). However, in 2009, the transoral approach to oropharyngeal cancers was approved by the FDA.[83,84] While this approach has not been commonly adopted, European studies have shown promise.[85]

CARDIAC (SEE ALSO CHAPTER 54 ANESTHESIA FOR CARDIAC SURGICAL PROCEDURES)

Robotic surgery has been performed in cardiac operating rooms for quite a few years. In 1997, internal mammary artery harvesting was first performed using an endoscope by Nataf et al.[86] The following year, Loulmet and colleagues[87] reported the first completely endoscopic coronary artery bypass surgery. Cardiothoracic applications of robotic-assisted surgery have expanded to include atrial septal defect closures,[88-90] mitral valve repairs,[91] patent ductus arteriosus ligations,[92] totally endoscopic coronary artery bypass grafting,[93,94] minimally invasive atrial fibrillation surgery,[95,96] and left ventricular pacemaker lead placement.[97] Although minimally invasive surgery may eventually make surgical sternotomy obsolete, surgeons still must be prepared to convert to an open sternotomy if the need arises.

Anesthesiologists must be familiar with cardiac and thoracic anesthesia when performing robotic-assisted cardiac procedures. The ability to perform one-lung ventilation and manage the associated physiologic changes are mandatory proficiencies, and the ventilation strategy is like that typically used during thoracic surgery. Poor pulmonary function test results or pulmonary hypertension may be contraindications to robotically assisted cardiac surgery since prolonged one-lung ventilation may not be tolerated. Additionally, many anesthesiologists turn to transesophageal echocardiography (TEE) to monitor cardiac physiology under anesthesia.

To allow surgical exposure for robotic cardiac surgery, several cannulae must be placed before cardiopulmonary bypass may be initiated. Femoral vessels are usually accessed. However, as iatrogenic dissection of the femoral arteries may occur, some hospitals require preoperative imaging to evaluate for atherosclerotic disease. Other centers use TEE to guide venous cannulation of the right atrium/inferior vena cava junction or superior vena cava (Fig. 71.10). These cannulae are often flushed with 5000 units of heparin, or infused with a heparin drip to maintain patency.

In addition to the cannulae required for cardiopulmonary bypass, an additional cannula is advanced into the pulmonary artery to vent the heart and to allow surgical visualization. Again, TEE can be helpful with placement of these venting cannulae.

Mitral Valve Replacement

In 1997, two different reports of robotic-assisted mitral valve replacement appeared in the literature. In November 2002, the FDA approved the use of robot-assisted surgery for this procedure. For the robotic mitral valve procedure to be successful, a patient must be anesthetized, and single-lung ventilation must be initiated. Patients are then positioned with their right shoulder elevated by 30 degrees while their pelvis remains supine. Keeping the pelvis in the supine position allows the femoral vessels to be more easily accessed.

After positioning, trocars are introduced into the fourth or fifth intercostal space by the surgical team and exposure is achieved before the robot is docked. It is imperative that the anesthesia team keeps the patient completely paralyzed from this point forward until the robot is undocked to minimize iatrogenic injury.

Cardiopulmonary bypass is subsequently initiated using femoral cannulae, and cardioplegia is introduced into the coronary vasculature. The ascending aorta is subsequently cross-clamped, and the mitral valve is replaced. Following replacement, the valve's function is evaluated using TEE.

The procedure concludes with the aortic cross-clamp removed, and the patient is weaned from cardiopulmonary bypass. The patient's double-lumen endotracheal tube is ultimately exchanged for a single-lumen endotracheal tube if the patient is to be intubated postoperatively. There are several reasons why a particular patient may not be a candidate for robotic mitral value surgery (Box 71.1).

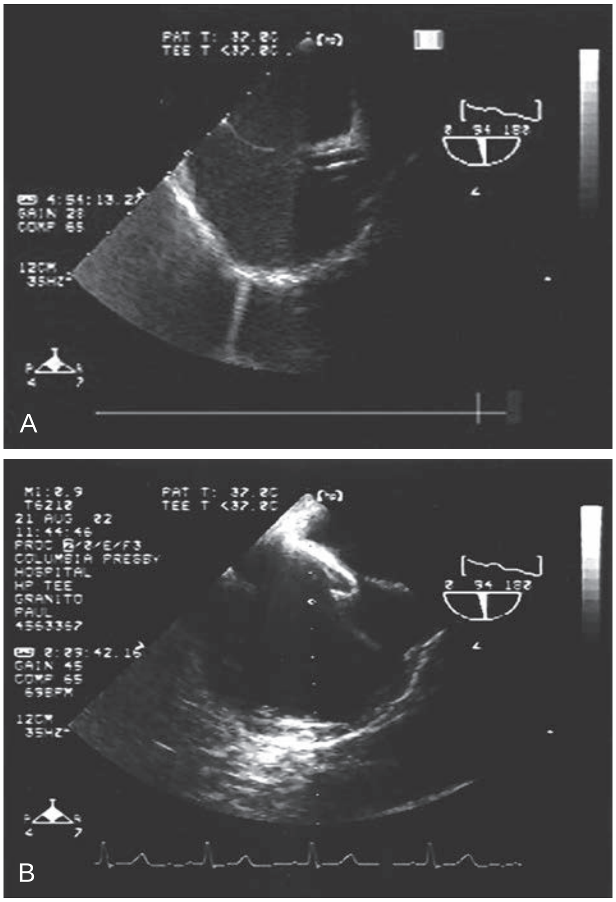

Fig. 71.10 (A) Ultrasound image of the superior vena cava cannula. (B) Ultrasound image, bicaval view, depicting the inferior vena cava containing a J guide wire. Both views are helpful in correctly placing cardiopulmonary bypass venous cannulae.

BOX 71.1 Exclusion Criteria for Robotically Assisted Mitral Valve Repairs

- Severely calcified mitral annulus
- Severe pulmonary hypertension
- Ischemic heart disease
- Surgery requiring multiple valve repairs
- Previous surgery to right hemithorax
- Severe aortic and peripheral atherosclerosis

Coronary Artery Bypass Grafting

Robotic-assisted coronary artery bypass graft surgery is a safe and effective procedure, which is gaining in popularity.[94] Potential exclusion criteria for robotic coronary artery bypass grafting are listed in Box 71.2.[96]

For coronary artery bypass graft procedures, patients are prepared and monitored for anesthesia in a manner similar to mitral valve surgery. Cardiac function and cannulae

BOX 71.2 **Exclusion Criteria for Robotically Assisted Endoscopic Coronary Artery Bypass Grafting**

- Contraindications to one-lung ventilation
- Ejection fraction <30% or decompensated heart failure (NYHA class III or IV)
- Moderate to severe aortic and mitral valve disease
- MI in preceding 30 days or MI requiring emergent CABG or postinfarction angina
- Calcified or intramyocardial LAD artery or diffuse LAD artery disease
- Large heart within left chest
- Morbid obesity (BMI > 35 kg/m^2)
- Severe peripheral vascular disease
- Severe noncardiac health issues
- Previous thoracic surgery, pleural adhesions, or radiation therapy of mediastinum or thorax

BMI, Body mass index; *CABG*, coronary artery bypass graft; *LAD*, left anterior descending; *MI*, myocardial infarction; *NYHA*, New York Heart Association.

placement are verified using TEE. In addition, anesthesiologists may consider pulmonary artery catheters when appropriate.

To harvest the internal mammary artery for the bypass grafts, single-lung ventilation is initiated using a double-lumen tube or a standard endotracheal tube with a bronchial blocker. Once single-lung ventilation commences, the patient is placed in a modified right lateral decubitus position, a 30-degree tilt to the right from the supine position. External defibrillation and pacing pads are then applied to the left posterior chest and anterolateral right chest. To improve surgical exposure to the left internal mammary artery, the left arm is raised. Conversely, to allow better exposure to the right internal mammary artery, the right arm is subsequently raised (Fig. 71.11). Very minimal CO_2 insufflation (usually 5-10 mm Hg) is needed to displace the mediastinal fat pad and allow surgical exposure. When single-lung ventilation is initiated and the left hemithorax is insufflated with CO_2, bilateral arteries are often able to be visualized.[98] When cardiopulmonary bypass is anticipated, the left femoral artery is cannulated with a 17- or 21-Fr remote access perfusion catheter (Fig. 71.12) with an aortic occlusion balloon. The remote access perfusion catheter

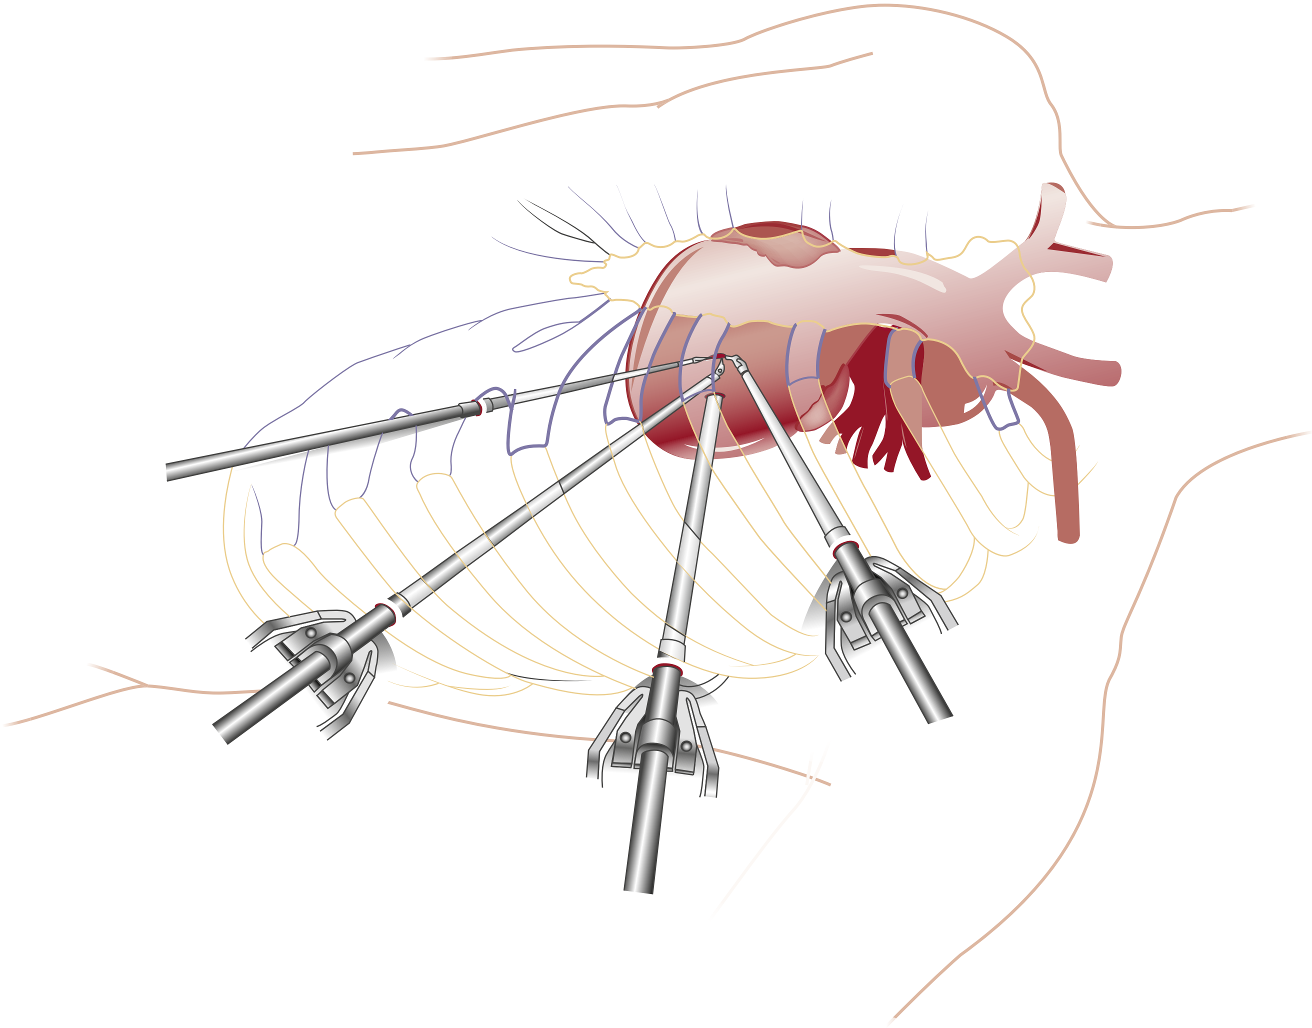

Fig. 71.11 Incision ports for coronary artery bypass grafting. Trocars are placed in the third, sixth, and eighth intercostal spaces. Similar port positions are used for bilateral internal mammary artery dissection.

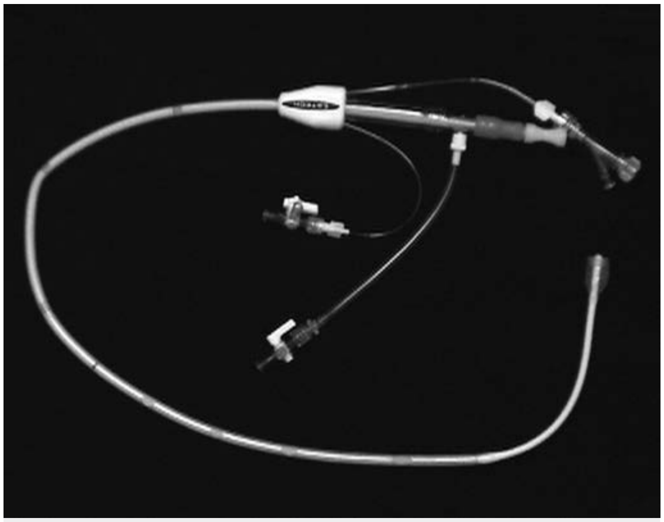

Fig. 71.12 Remote Access Perfusion (Estech Systems, Plano, TX, USA) catheter. The endovascular catheter has a cylindrical balloon for endovascular aortic clamping. The catheter provides anterograde perfusion of the aortic arch at a rate of 5 L/min.

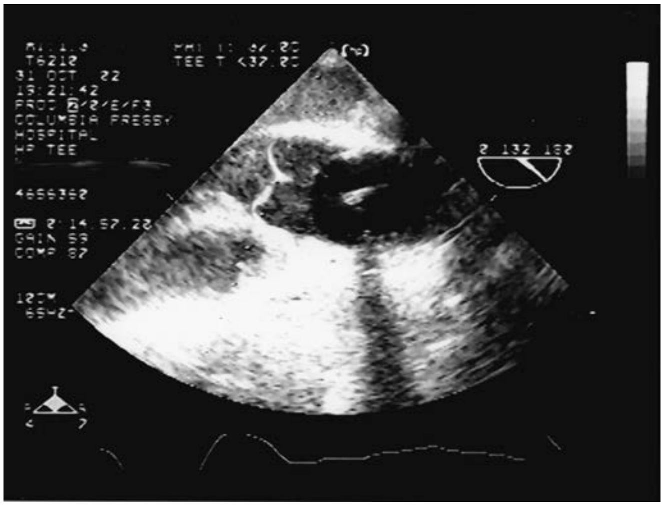

Fig. 71.13 Ultrasound image of Remote Access Perfusion (Estech Systems, Plano, TX, USA) catheter balloon in situ. Transesophageal echocardiography allows the anesthesiologist to keep track of the migration of the catheter balloon. The balloon should be positioned in the ascending aorta 2 to 4 cm distal to the aortic valve. Right radial pressure catheter signal damping can detect balloon malposition when occlusion of the innominate artery occurs.

allows anterograde flow of 4 or 5 L/min. The aortic cannula is subsequently positioned in the ascending aorta, roughly 2 cm above the aortic valve, using TEE (Fig. 71.13). The endovascular balloon is inflated with a volume equal to the diameter (in milliliters) of the sino-tubular junction of the aorta. A balloon pressure greater than 300 mm Hg usually provides complete occlusion of the aorta.[99] Residual flow around the balloon can be seen and monitored with color flow on TEE. The use of bilateral radial arterial lines is useful in detecting the migration of the occlusion balloon toward the innominate artery. Proximal migration of the balloon can be seen most easily with TEE, preventing balloon herniation through the aortic valve.

Single-lung ventilation is then initiated, and the right lung is collapsed. By insufflating the right hemithorax with CO_2, three 1-cm ports may be placed at the third, fourth, and fifth intercostal spaces on the anterior axillary line (see Fig. 71.11). The patient's pericardium is then dissected to expose the heart. Arrhythmias in the early postoperative period are common. Antiarrhythmics, such as amiodarone and β-adrenergic blockers, can be helpful.[100-102]

ROBOTIC-ASSISTED THORACOSCOPIC SURGERY (SEE ALSO CHAPTER 53 ANESTHESIA FOR THORACIC SURGERY)

Video-assisted thoracoscopic surgery (VATS) is a commonly performed procedure for cancerous tumor resection (wedge resections and lobectomies), esophagectomy, hiatal hernia, and lung volume reduction.[103-107] VATS is preferred to open procedures when possible to reduce length of stay, blood loss, pain, and morbidity as long as clinical outcomes are equivalent. However, as it is difficult to do complex surgeries (e.g., a pneumonectomy or a thymectomy) using minimally invasive techniques such as VATS, the hope is that a robotic approach (robotic-assisted thoracoscopic surgery [RATS]) will allow the application of minimally invasive techniques to these more complex surgeries and generate some of the same benefits as open procedures. While several centers are exploring RATS lobectomies, segmentecomies, and mediastinal mass resections, RATS pneumonectomies have been reported at only a couple of pioneering centers.[108] Robotic-assisted surgery usually increases the operative time and cost compared to its laparoscopic alternative.[109]

Robotic-assisted thoracoscopic surgery presents with similar challenges to robotic-assisted cardiac surgeries. Accommodating a more rigid chest wall and moving heart, lungs, and mediastinum can be challenging. In addition, initiating and maintaining prolonged one-lung ventilation and hemodynamic instability associated with CO_2 insufflation of the hemithorax presents unique concerns. Despite these challenges, the robot has been specifically used for thymectomies, mediastinal mass resections, fundoplications, esophageal surgery, and pulmonary lobectomies.[110-112]

Patient positioning is particularly important to expose largely inaccessible areas, as mediastinal structures are heavy, mobile, and change position in response to gravity (see Chapter 53). Supine or slight lateral decubitus position (raising one side 15-30 degrees) is most ideal for anterior mediastinum pathology. This position requires the elevated arm to be at the patient's side as far back as possible to allow the robot to dock successfully. However, hyperabduction of the elevated arm can cause a brachial plexus injury.[111] A full lateral decubitus position (90 degrees) may be optimal for hilar masses and lobectomies. Alternately, a prone or slightly modified prone position can create better exposure for posterior mediastinal masses.[113]

Since the patient will generally be rotated 90 degrees to allow the robot to dock, it is important to achieve lung isolation prior to rotation. Also, the anesthesia circuit, intravenous line, and arterial line tubing may require extensions. It is suggested that the circuit and lines be combined into one bundle to move them out of the way of surgical personnel and monitoring devices. It is also recommended to have two large-bore intravenous lines since the arms will be difficult to access once the robot is docked. The patient undergoing RATS should generally have an arterial line placed prior to the robot being docked to allow for close monitoring of blood pressure and $PaCO_2$. Intraoperative confirmation of lung isolation will be difficult, so a plan of how to access the airway with a fiberoptic bronchoscope should be established prior to initiating the robotic portion of the case. It is important to note that a failure of lung isolation will result in an inability to complete the surgery via RATS.[110]

CO_2 insufflation helps achieve adequate surgical exposure by mobilizing the mediastinum and simultaneously compressing the lung away from the operative site. Unfortunately, CO_2 insufflation can lead to hemodynamic instability and difficultly with hypercapnia during one-lung ventilation. It can also cause venous gas embolism, decreased venous return, and cardiac collapse if right heart failure develops.

The anesthesiologist must also be ready for potential conversion to open thoracotomy due to bleeding or an inability to obtain adequate surgical exposure.[111] In a recent meta-analysis, the incidence of conversion from RATS to open thoracotomy during pulmonary resections was 0% to 19%.[114,115] The learning curve for new surgeons is also quite steep during the first 20 cases. An increase in operative issues must be anticipated for surgeons learning to use the robot.[114,115]

Another possible pitfall of RATS is that damage to the pleura may allow CO_2 insufflation to spread to the ventilated lung causing difficult ventilation and possibly causing a tension pneumothorax or severe subcutaneous emphysema—both of which can produce hemodynamic compromise.[114]

Studies comparing outcome data from VATS versus RATS in more common procedures are increasing. As might be expected for any complex procedure, outcomes for RATS lobectomies are better at high-volume centers.[116] As shown in other surgical disciplines, longer duration RATS lobectomies have similar outcomes to VATS lobectomies. However, robotic surgery does have increased costs in comparison to laparoscopic alternatives.[117,118] In an investigation of open versus VATS versus RATS treatment of early-stage thymomas, the robotic approach was associated with a reduced length of stay and had a similar complication profile to VATS.[119] In the case of esophagectomies, RATS—while having a longer surgical duration than a minimally invasive approach—has a similar outcome profile.[120]

As robotic instead of open approaches are starting to be used on more complex surgeries, we expect to see an improvement in patient outcomes and possibly a reduction in costs.[108,121]

Summary

Anesthesia for robotic surgery is an exciting and dynamic field. As surgeons and patients look for new innovations and technologically rich approaches to healthcare, it is reasonable to expect that more operations will be performed using robotic techniques. However, there is a real need to investigate the outcomes and costs of a robotic approach versus a more traditional approach. More data are needed to identify the type of cases and patient populations that will improve patient outcomes and reduce costs via robotic surgery. Recognizing the unique physiologic changes and positioning challenges that accompany robotic surgeries will allow anesthesiologists to best care for their patients.

Ambulatory (Outpatient) Anesthesia

IAN SMITH, MARK A. SKUES, and BEVERLY K. PHILIP

KEY POINTS

- The use of ambulatory surgery continues to increase, mostly as a result of less invasive surgical techniques, improved patient selection and preparation, and an expansion of office-based practice.
- Few absolute contraindications exist to ambulatory surgery. Patients should not be excluded on the basis of arbitrary limits, such as age, body mass index, or American Society of Anesthesiologists physical status classification system.
- Effective preoperative assessment is required to evaluate and prepare patients and is essential for the delivery of safe, high-quality, and efficient ambulatory surgical care.
- Many anesthetics and techniques can be used for ambulatory surgery. Of prime importance, provider experience and careful attention to detail are required to deliver high-quality rapid recovery with minimal side effects.
- Spinal anesthesia may extend the range of patients and procedures suitable for ambulatory surgery, but it requires the use of small doses of bupivacaine combined with opioids or short-acting local anesthetics to avoid prolonged recovery.
- Sedative techniques can facilitate a wide variety of procedures performed in the hospital, office, or remote settings. However, sedation is no safer than general anesthesia and requires the same standards of personnel, monitoring, and perioperative care as for patients undergoing general or regional anesthesia.
- Multimodal analgesia, using combinations of local or regional anesthesia, acetaminophen, and nonsteroidal antiinflammatory drugs, provides effective relief of pain. The reduced need for opioids decreases the incidence and intensity of adverse effects.
- Antiemetic prophylaxis should be based on individual patient risk. Multimodal regimens are required for patients and procedures known to be associated with increased risk for perioperative nausea and vomiting.
- Patients should be discharged with written instructions concerning aftercare, return to normal activities, follow-up evaluation, and a contact telephone number. This advice must include early warning signs and the appropriate action to take.
- Ambulatory surgery remains very popular with patients with infrequent rates of adverse events and complications.

Introduction

Ambulatory surgery has its origins in Glasgow, Scotland, where, between 1898 and 1908, James Henderson Nicoll performed almost 9000 ambulatory surgical procedures on children, nearly half of whom were younger than 3 years of age.[1] Contrary to the prevailing philosophy, which advocated prolonged bed rest after surgery, Nicoll encouraged early mobilization and home follow-up by a visiting nurse to reduce high cross-infection rates and overcome bed shortages and financial constraints. A few years later, Ralph Milton Waters opened his Downtown Anesthesia Clinic in Sioux City, Iowa, allowing adult patients to return home within a few hours of difficult dental extractions, abscess drainage, or reduction of minor fractures.[2] Further progress was slow until the dangers of prolonged bed rest and the economic advantages of shorter stays began to be recognized toward the middle of the twentieth century. The first hospital-based ambulatory surgical units were opened in Grand Rapids, Michigan, in 1951, and in Los Angeles, California, in 1952, and somewhat later at London's Hammersmith Hospital in the United Kingdom in 1969.[3] At the same time, the first freestanding ambulatory surgery center opened in Phoenix, Arizona,[4] rapidly followed by many others across North America in the 1970s and 1980s.

The development of ambulatory anesthesia as a recognized subspecialty was enhanced by the formation of the Society for Ambulatory Anesthesia (SAMBA) in 1984[5] and the British Association of Day Surgery in 1989. These and nine other national societies came together in 1995 to form the International Association for Ambulatory Surgery (IAAS), an umbrella organization dedicated to the worldwide promotion of ambulatory surgery.

Ambulatory surgery has expanded far beyond the performance of simple procedures on healthy patients. Currently, a broad range of major procedures are performed on patients who frequently have complex preexisting medical conditions. The availability of improved anesthetic and analgesic drugs minimizes the anesthetic side effects and facilitates the recovery process, as do the increasing availability of minimally invasive surgical techniques. Equally important has been a philosophical change that challenged outdated and conservative practices, demanding unnecessary postoperative inpatient admission. Ambulatory surgery now accounts for approximately 80% of the elective surgeries in the United States.[6] Ambulatory surgery also constitutes a large proportion of elective surgical activity in the United Kingdom and increasingly in many other countries worldwide, although rates for individual procedures still vary.[7]

DEFINITIONS

Although ambulatory surgery is widely practiced, the precise definition can vary across countries and healthcare systems. For consistency, we have used the definition proposed by the cofounder of the IAAS: "A surgical day case is a patient who is admitted for investigation or operation on a planned non-resident basis and who none the less requires facilities for recovery. The procedure should not require an overnight stay in a hospital bed."[8] This definition requires the patient to be managed with the intention of same-day discharge from the outset, in addition to admission, operation, and discharge all occurring on the same calendar day. Including management intention in the definition ensures no incentive is provided to discharge a planned inpatient at short notice, who would be without all of the preparation and support required for optimal postoperative care.

Short-stay surgery embraces all of the principles of ambulatory surgery and includes a postoperative overnight hospital stay. Extended observation may be prudent for certain patients with significant comorbidities, lack of social support, or for those who have undergone a procedure that is either too extensive or performed too late in the day to be compatible with same-day discharge. We have included short-stay surgery in this chapter because the objectives of minimizing physiologic disturbance to improve the quality of recovery and reduce the length of stay are the same as those of ambulatory surgery and much of the perioperative management is similar.

Benefits of Ambulatory Surgery

In order for surgery to be performed on an ambulatory basis there must be reduced tissue trauma, enhanced recovery with minimal adverse events, and the provision of effective postoperative analgesia, appropriate information, and postoperative support. Patients appreciate the more efficient scheduling of surgery, and the comfort and convenience of recovering in the familiar home environment. There are also financial advantages associated with ambulatory surgery due to the elimination of costs associated with overnight admission. In both the United States and the United Kingdom, procedures that are compatible with ambulatory surgery receive the same payment (from insurance companies and regional budget holders, respectively), irrespective of the length of stay. Therefore, if a patient does stay overnight, the extra costs are borne by the facility. Since 2010 in the United Kingdom, a higher level of funding has been available for an increasing number of procedures when performed on an ambulatory basis,[9] in order to incentivize best practice and finance any necessary pathway redesign.

Facilities for Ambulatory Surgery

In the United States, the American Society of Anesthesiologists (ASA) provides guidelines for ambulatory surgical facilities,[10] including statements pertaining to adherence to local regulations, staffing requirements, and minimum equipment standards. Quality standards are set and enforced by government regulation, licensing, or accreditation. In the United States and Canada, hospital-based ambulatory surgical facilities receive accreditation through The Joint Commission (TJC), Det Norske Veritas (DNV), and the Healthcare Facilities Accreditation Program. Ambulatory surgery centers and office-based surgery locations can receive accreditation through the Accreditation Association for Ambulatory Health Care, American Association for Accreditation of Ambulatory Surgery Facilities, or TJC. In the United States, the Centers for Medicare & Medicaid Services (CMS) has its own inspection program in addition to accepting accreditation decisions from the listed organizations.

A multitude of designs exist for ambulatory surgical facilities. Some have been purpose designed, and others have evolved by adapting existing facilities. The facilities delivering ambulatory care services also vary by country, but they can be broadly categorized into four models of care, each with its own advantages and disadvantages.[11]

HOSPITAL INTEGRATED

The simplest model of ambulatory surgery is one with shared inpatient surgical facilities, but with separate areas for preoperative preparation and recovery of ambulatory patients. This model of care is most often inefficient and brings the risk for ambulatory procedures being delayed or even canceled in favor of urgent or emergent inpatient procedures. However, by dedicating certain operating sessions to ambulatory surgery and using strict protocols, efficiency in one such unit has been described as almost equal to that of a self-contained unit.[12] The design is flexible, allowing the proportions of ambulatory and inpatient surgery to vary from day to day, and, as new procedures are transferred to ambulatory surgery, it does not require duplication of equipment and skills in a separate facility.

HOSPITAL SELF-CONTAINED

These self-contained units are functionally and structurally separate from inpatient facilities with their own reception, admission areas, operating rooms, recovery areas, and administrative facilities. This design promotes a patient-focused flow of care. It ensures functional separation from urgent and emergency work while maintaining the accessibility of resources available in the main hospital. In many ways it is an ideal model of care. However, the local capacity for ambulatory surgery may be reached, and duplication of operating room equipment and skills may then occur for those procedures still commonly performed on both an ambulatory and inpatient basis.

FREESTANDING

Freestanding ambulatory surgery centers ensure complete separation of perioperative care from inpatient and emergency work. This improves efficiency and allows complete focus on a workflow designed for ambulatory care. While rare perioperative complications may occur that require elevation of care or additional resources, appropriate patient selection and preparation minimize this risk. Some freestanding units have the capacity for overnight stays to provide additional nurse-monitored recovery. However, all freestanding units must have a detailed plan for the care of patients who need urgent or emergent transfer to a nearby hospital. Ambulatory surgery centers vary from highly specialized, single-surgery facilities performing ambulatory total joint replacements or bariatric procedures to those that can accommodate multiple specialties and support a variety of service lines.

OFFICE-BASED

Performing ambulatory surgery, diagnostic procedures, or both in a facility associated with a physician's office is a rapidly expanding model of care within the United States.[6] The main advantages are increased convenience for the patient and surgeon, and lower total procedure costs. Office-based services and facilities have historically been subject to less regulatory requirements when compared to those imposed on ambulatory surgery centers. Furthermore, they may have more significant limitations with respect to equipment, personnel, and environment along with reduced capability when managing perioperative complications. These limitations, however, are rapidly changing. In the United States, physician offices that provide services that include procedures involving moderate to deep sedation or general anesthesia may be subject to state regulatory requirements for accreditation and adherence to standards with respect to governance, facility environment of care, availability of equipment, credentialing of staff, and continued medical education for personnel. A more detailed discussion of office-based anesthesia can be found later in the chapter.

Patient Selection Criteria

SURGICAL FACTORS

The development of minimally invasive surgery, improvements in surgical technique and pain control, and the availability of shorter-acting anesthetics have dramatically increased the range of surgical procedures compatible with same-day discharge. While the duration of surgery has traditionally been a determinant of outcome, the extent of surgical trauma now appears to be the more significant determinant. There should be no expectation of significant blood loss, large perioperative fluid shifts, or the need for complex or specialized postoperative care. Surgical complications remain the single greatest cause of unanticipated hospital admission.[13,14] In the United States and the United Kingdom, an overnight stay for patients who have undergone an ambulatory surgery procedure in any venue receives no additional payment, so the extra costs are borne by the facility. The British Association of Day Surgery publishes a directory of over 200 different surgical procedures and suggests aspirational targets for the proportions of each that are suitable for either ambulatory or short-stay surgery.[15] A selection of these are shown in Table 72.1.

TABLE 72.1 A Selection of Surgical Procedures Which can be Performed on an Ambulatory Basis

Specialty	Examples of Surgical Procedures
Breast surgery	Excision/biopsy including wide local excision, sentinel node biopsy, simple mastectomy, microdochectomy, and other operations on nipple
General surgery	Perianal fistulae, pilonidal sinus, hemorrhoidectomy, open or laparoscopic hernia repair, laparoscopic cholecystectomy, adrenalectomy, splenectomy, fundoplication, gastric banding
Gynecology	Cervical surgery, laparoscopic tubal ligation, oophorectomy, hysterectomy, anterior and posterior repair
Head and neck	Dental procedures, excision of salivary glands, thyroidectomy, and parathyroidectomy
Ophthalmology	Cataract surgery, strabismus surgery, vitrectomy, nasolacrimal and all eyelid surgery
Orthopedics	Diagnostic and therapeutic arthroscopic surgery, anterior cruciate ligament repair, carpal tunnel release, bunion surgery, fracture reductions and removal of metalwork, lumbar microdiscectomy, minimally invasive hip surgery, unicompartmental knee surgery
Otolaryngology	Myringotomy and tympanoplasty, rhinoplasty, procedures on nasal septum and turbinates, polypectomy, adenotonsillectomy, laryngoscopy, and endoscopic sinus surgery
Urology	Endoscopic bladder and ureteric surgery, transurethral laser prostatectomy, circumcision, orchidectomy, laparoscopic nephrectomy, pyeloplasty, and prostatectomy
Vascular surgery	Varicose vein surgery, dialysis fistula creation, transluminal arterial surgery

Laparoscopic cholecystectomy is now a routine ambulatory surgical procedure in many countries, and increasingly same-day discharge is seen as safe and beneficial after a variety of advanced laparoscopic procedures, including fundoplication,[16] hysterectomy,[17] nephrectomy,[18] pyeloplasty,[19] radical prostatectomy,[20] and gastric banding.[21] Minimally invasive approaches have also facilitated same-day discharge following unicompartmental knee[22] and hip arthroplasty.[23,24] One series of 2000 patients undergoing laparoscopic Roux-en-Y gastric bypass for morbid obesity reported 84% being discharged within 23 hours with a readmission rate of less than 2%.[25]

Even specialties like neurosurgery, traditionally associated with complex inpatient care, have begun to embrace day surgery. Same-day discharge of selected patients undergoing awake craniotomy for supratentorial tumors was first described in 2001.[26] More recently, some patients requiring general anesthesia for tumor resection[27] and even aneurysm clipping[28] have been discharged on the day of surgery. Increasingly, a number of non-elective procedures, such as abscesses, incarcerated hernia repairs, and appendectomies, are being managed through day surgery pathways.[29] In parallel, several less invasive procedures, such as diagnostic or therapeutic hysteroscopy, are moving from ambulatory surgery into the procedure room, outpatient clinic, or office.[30]

While postoperative pain control in the home environment may present substantial challenges, perhaps the greatest barrier to the development of ambulatory surgery is conservatism, based on incorrect perceptions and concern about serious complications that might occur following discharge. For example, despite convincing data that most primary hemorrhages are evident within 6 to 8 hours of tonsillectomy,[31,32] an overnight stay is still routine in some countries while others discharge 80% of patients or more on the day of surgery.[7] Similarly, ambulatory thyroid surgery was first shown to be safe and effective in 1986,[33] yet its widespread adoption has been slow,[34] predominantly because of concerns about bleeding and airway compromise. Such complications are rare, especially when surgery is undertaken by specialists who perform a high volume of cases with assiduous hemostasis, allowing short times to discharge to be achieved.[35] Performing thyroidectomy under local anesthesia also appears to increase ambulatory surgery rates,[36] perhaps because of the careful surgical technique required. In the case of breast surgery, concerns about postoperative psychological support has delayed transfer of mastectomy and other cancer operations into ambulatory care in the United Kingdom, although it is now recognized that early discharge improves the psychological well-being of these patients by minimizing the time away from home.[37] Challenging conventional wisdom also may be beneficial; for example, discontinuing the routine use of drains after mastectomy or axillary node clearance does not increase morbidity, including from wound seroma, while facilitating same-day discharge.[38] Day surgery management of breast cancer is associated with fewer complications than inpatient care.[39]

MEDICAL FACTORS

In the past, ambulatory surgery has relied on relatively rigid patient selection criteria in the attempt to limit the occurrence of postoperative complications. In practice, however, most of these criteria predict the occurrence of treatable perioperative adverse events, but not the need for unanticipated admission or readmission.[40] Although an index combining age, length of surgery, and preexisting conditions, such as peripheral or cerebrovascular disease, can identify a group at higher risk for hospital admission, the specificity is poor and same-day discharge is still the most likely outcome.[41] Ambulatory surgery is very safe, with a perioperative mortality less than 1 in 11,000,[42] better than that in the general population. More recent studies have confirmed the continuing safety of ambulatory surgery, despite increasing surgical and patient complexity.[43-45]

Relatively few absolute contraindications now exist to ambulatory surgery. Patient suitability should be assessed on the basis of overall health, taking into account both the risks and benefits of early discharge, and certainly not determined by arbitrary limits, such as age, body mass index (BMI), or ASA physical status.[46] Chronic conditions should be relatively stable and must be optimally treated before any elective procedure, irrespective of the planned postoperative management. Many stable chronic diseases, such as diabetes, asthma, or epilepsy, are often better managed by the patients than by the perioperative team, and ambulatory surgery facilitates this by easing the disruption to their daily routine.[46] A distinction should be made between preexisting conditions that make a patient more difficult to manage on the day of surgery and those that increase the occurrence of late postoperative problems, which are a relative contraindication to ambulatory surgery.[47]

A good example is obesity, which is associated with numerous perioperative problems for the surgeon, anesthesiologist, and operating room personnel (see also Chapter 58). Safe care of the obese patient may require the availability of experienced staff and specialized equipment, such as longer instruments and wider operating trolleys but any risks are resolved soon after immediate recovery and are not prevented by postoperative overnight hospitalization. Obese patients benefit from ambulatory management with early mobilization, the use of short-acting drugs, and avoidance of opioid analgesia.[47] Obesity does not increase the rate of unanticipated admission, postoperative complications, readmission, or other unplanned contact with health professionals following discharge.[48] Even morbid obesity (BMI > 40 kg/m^2)[46] and super obesity (BMI > 50 kg/m^2)[49] are no longer considered absolute contraindications to same-day discharge. Obesity increases the likelihood of further comorbidities, but these should be evaluated individually.

Obstructive Sleep Apnea

Obstructive sleep apnea (OSA) occurs in the general population but is much more common in obesity. Nonetheless, most cases can be managed safely and effectively on an ambulatory basis.[50] Perioperative problems such as difficult tracheal intubation and airway obstruction should be anticipated.[51] However, patients undergoing more invasive surgery, especially involving the chest or airway, or those requiring large doses of perioperative opioids, may be less suitable.[50] Frequently, OSA is suspected but has not yet been definitively diagnosed and treated. A simple questionnaire, supplemented with some basic measurements (e.g., STOP-Bang), can identify most patients at high risk for OSA,[52] but there is insufficient evidence to recommend delaying surgery until the diagnosis is confirmed.[53] In children, OSA is now one of the main indications for tonsillectomy and this has been seen as a relative contraindication to ambulatory surgery. However, one recent study has shown that same-day discharge is still safe in the absence of other comorbidities.[54]

Age

Medical and social problems increase with age and should be evaluated and managed individually rather than applying an arbitrary upper age limit for ambulatory surgery. The risk for death or readmission within 7 days of surgery in patients over 65 years of age are 41/100,000 and 2.53%, respectively.[55] Although somewhat more frequent than values from younger patients, the major risk factors appear to be very advanced age (older than 85 years of age), more invasive surgery, and recent inpatient hospital care.[55] The frequency of perioperative adverse cardiovascular events also increases with age. Overall, older patients had a twofold increase in the risk for intraoperative adverse cardiovascular events; however, this was seen not as a contraindication to ambulatory surgery but rather as indicating the need for more careful intraoperative management.[56] In contrast, the incidence of postoperative complications seems to be reduced in older patients.[56,57] In particular, older patients appear to experience far less postoperative pain, dizziness, nausea, and vomiting than younger patients,[56,58] and do not require a higher rate of unplanned admission or readmission. One study suggests a reduced incidence of postoperative cognitive dysfunction in older patients after ambulatory surgery compared to similar procedures performed on an inpatient basis,[59] presumably because of the use of short-acting anesthetic techniques and reduced separation from their familiar home environment. Reducing length of hospital stay after hip and knee surgery appears to confer similar benefits.[60]

At the other age extreme, the lower limit for ambulatory surgery may vary depending on the expertise and specialization of the individual facility. Premature babies have a higher risk for postoperative apnea, and hence ambulatory surgery may be inadvisable until they have reached an appropriate postconceptual age (PCA). Evaluation of several historic and retrospective studies suggests the risk for postoperative apnea is less than 5% once PCA exceeds 48 weeks, provided gestational age was at least 35 weeks, the infant was not anemic, and no apnea occurred in the recovery room.[61] However, because considerable variability exists in the incidence of apnea and the relatively small sample size of these studies, the PCA at which risk becomes acceptably low is controversial,[62] with a value of 60 weeks most commonly taken as the cutoff for ambulatory management.[63,64] Caffeine administration appears to markedly reduce the incidence of postoperative apnea in babies who were premature,[65] but this is not seen as a substitute for careful patient selection.[63] Spinal anesthesia may offer advantages to infants who were premature undergoing abdominal surgery in the first week of life, but it is distressing to the infant and has a high (28%) failure rate.[66] Compared with older studies involving more soluble anesthetics, sevoflurane and desflurane were associated with lower rates of postoperative apnea after hernia surgery in infants born at less than 37 weeks gestation and under 47 weeks PCA.[67] Although no airway interventions were required to manage apnea, episodes still occurred throughout the 12-hour postoperative observation period and were equally common with either anesthetic.[67]

Cardiovascular Disease

Hypertension is the most common cardiovascular disease and has been a frequent cause for delay and cancellation of ambulatory surgery. Although hypertension is an important risk factor for long-term health, a meta-analysis of nearly 13,000 patients showed that it increased the risk for perioperative complications by only 1.35 times,[68] an amount that may be clinically insignificant. In ambulatory surgery patients, hypertension resulted in an approximate 2.5-fold increase in the risk for perioperative cardiovascular events,[57] but these were relatively minor. Hypertension is not an independent risk factor for perioperative cardiovascular complications if the diastolic pressure is less than 110 mm Hg.[69] Higher arterial blood pressures may predispose to perioperative ischemia, arrhythmias, and cardiovascular lability, but no clear evidence indicates that deferring surgery reduces perioperative risk.[68] In the United Kingdom, patients with documented blood pressures below 160 mm Hg systolic and 100 mm Hg diastolic in the community can be accepted for elective surgery without further measurement.[70] In practice, poorly controlled hypertension is usually identified at the preoperative evaluation and can be treated before surgery is scheduled. Delaying surgery until hypertension is controlled is unlikely to be beneficial.[71]

Patients with known hypertension should continue to take their chronic medication, especially β-adrenergic blockers. β-Adrenergic blockers should not be abruptly stopped,[72] and it may be more likely that they will be unintentionally omitted if patients are advised to take all of their cardiac medications up to and including the day of surgery.[73] Controversy surrounds angiotensin-converting enzyme inhibitors (ACEIs) and angiotensin receptor blockers (ARBs). It has been considered “reasonable”[74] to continue these, as any hypotension after induction of anesthesia is usually transient and responds to intravenously administered fluids and repeated vasopressor administration. However, evidence is accumulating of an increase in mortality, stroke, and myocardial injury if ACEIs and ARBs are continued,[75] and current practice is to hold these on the day of surgery.

Patients are generally unsuitable for ambulatory surgery if they have severe unstable angina that causes marked limitation of activity or pain at rest. In the absence of complications, such as arrhythmias or ventricular dysfunction, cardiac risk after myocardial infarction or revascularization procedures returns to baseline after 3 months.[76] Exercise tolerance is a major determinant of perioperative risk[76] and the inability to climb a flight of stairs (~4 metabolic equivalent tasks of activity) is highly predictive (89%) of a postoperative cardiopulmonary complication.[77]

Patients taking anticoagulants and antiplatelet drugs require careful evaluation to balance the risk for perioperative bleeding against the risk in withholding therapy. For minimally invasive procedures, the international normalized ratio can be briefly decreased to the low or subtherapeutic range, with the usual dose of oral anticoagulation resumed immediately after the procedure.[72,73] If the risk for bleeding or thromboembolism is high, low-molecular-weight heparin can be used as bridging therapy.[78] Patients are increasingly being managed with oral direct thrombin or factor Xa inhibitors (e.g., dabigatran, apixaban, rivaroxaban, and edoxaban). The effects of these agents are not reliably measured by commonly used coagulation tests, such as prothrombin time and activated partial thromboplastin time,[79] but their shortened half-lives may make bridging therapy unnecessary. Antiplatelet therapy should be continued for the recommended intervals in patients with bare metal and drug-eluting coronary artery stents, because premature discontinuation is associated with a 25% to 30% risk for stent occlusion, which in turn has a more than 60% risk for myocardial infarction and 20% to 45% risk for death.[80]

SOCIAL FACTORS

In general, if a patient's living arrangements were adequate before surgery, they should also be suitable after surgery. Some adaptations may be necessary if the patient's mobility is severely compromised by their procedure—for example, by the use of casts. Access to a telephone to summon assistance is a minimum requirement, but is rarely problematic with the ubiquitous availability of mobile telephones. Patients usually live within a reasonable traveling distance of the surgical unit, but this may be impractical in rural or sparsely populated areas. Journeys of hundreds or thousands of miles are not unheard of in parts of Scandinavia after ambulatory surgery.[47] For patients who live far away, consideration should be given to the provision of emergency care close to home and for the comfort of the patient during the journey. Patients who choose to travel long distances after ambulatory surgery usually are very satisfied with their care.[81] Hospital hotels, which provide nearby accommodation but little or no nursing care, are a higher-cost alternative for the patient and have largely been abandoned as an impractical option.

A universal safety feature is to require all patients having surgery under general anesthesia or sedation to be discharged with a responsible adult escort and the recommendation to have someone stay with them for the next 24 hours. If the 24-hour companion is mandated, patients often disregard postoperative instructions and send their escorts away if they feel well at home.[82] In the United States, it is standard practice to require that patients who have received other than unsupplemented local anesthesia be discharged with a responsible adult[10]; if not, surgery is postponed. A Canadian single-institution study reported discharging patients alone when their escort fails to arrive,[83] yet this practice did not appear to increase emergency room visits or readmission rates within 30 days. The Association of Anaesthetists of Great Britain and Ireland has suggested that an escort may be required in most (but not all) cases,[46] with exceptions when the surgery is relatively minor and anesthesia brief so the patient is not compromised by the sedative effects of anesthesia or analgesia by the time of discharge.[47] If patients are discharged alone, they should not drive themselves home[84]; several serious accidents have occurred, especially after the use of sedative doses of benzodiazepines.

Preoperative Assessment

THE ROLE OF PREOPERATIVE ASSESSMENT

An effective preoperative assessment process is essential for the delivery of safe, high-quality, and efficient ambulatory surgery.[85] Rather than trying to select specific, low-risk groups of patients, ambulatory surgery is increasingly seen as the default option for a wide range of surgical procedures, with inpatient care chosen only for those with insurmountable barriers to early discharge. Other than identifying this small group of patients, preoperative assessment is primarily required to evaluate and optimize patients and to provide appropriate information (Table 72.2). These assessment and optimization functions can be further distilled into two key questions: "Is there any benefit to this patient of being in hospital overnight after surgery?" and "Is there anything that needs to be done to enable this patient to be a day case?"[85]

TABLE 72.2 The Four Key Functions of a Preoperative Assessment and Preparation Service for Ambulatory Surgery

Function	Examples
1. Identify absolute contraindications to ambulatory surgery	Inability to identify a responsible carer other than for minor surgery with full and rapid recovery anticipated; severe uncorrectable cardiovascular disease
2. Identify need for optimization	Patient requires further investigation, therapeutic modification, or intervention to improve functional status; identify a friend, relative, or neighbor to act as carer
3. Highlight issues for anesthesiologist or other staff (which may alter management but which do not preclude ambulatory surgery)	Potentially difficult intubation necessitating advanced airway management skills; malignant hyperpyrexia susceptible patient requiring trigger-free anesthetic; latex allergy; obese patient requiring operating table/trolley with high weight limit and extra width
4. Provide patient information	Written information on preoperative preparation, medication management, preoperative fasting, etc.

MECHANISMS AND TIMING OF PREOPERATIVE ASSESSMENT

The timing of preoperative assessment is crucial, because it must be done early enough in the pathway to allow for any necessary investigations and optimization without delaying the planned procedure. This becomes increasingly difficult as the interval between the decision to operate and the date of surgery becomes shorter. Ideally, preoperative assessment should immediately follow the decision to operate, by providing a "one-stop shop." This type of service, in which preoperative assessment immediately follows the surgical consultation, is highly valued by patients,[86] although it can be difficult to manage because of variations in the demand for the service. An alternative is to use a basic screening tool to identify those patients who can proceed directly to surgery and those who require further investigation or management (Fig. 72.1).

A case can be made for all patients to be seen in a preoperative assessment clinic; however, in practice this places a major demand on resources and is also inconvenient for patients who may need to take additional time off work. Screening allows many patients to undergo assessment by telephone or questionnaire, with clinic attendance required only if unexpected problems are uncovered or if requested by the patient. When telephone assessment was chosen for all young healthy patients scheduled for minor breast surgery, only 2% of patients had problems identified that required further assessment in the ambulatory surgery center.[87] By using a computerized information-gathering and triage tool, combined with some basic information about

Schedule for inpatient surgery

Fig. 72.1 Flowchart illustrating the basic process for selecting patients for ambulatory surgery. The pathway incorporates a screening process for patients who may not require a full face-to-face assessment in the clinic. (Modified and adapted from Smith I, Hammond C. Day case surgery. In: Radford M, Williamson A, Evans C, eds. *Preoperative Assessment and Perioperative Management*. Keswick: M&K Books; 2011:267–280. With permission.)

the planned procedure, approximately onethird of ambulatory patients did not need to see an anesthesiologist before the day of surgery.[88] This approach eliminates the need for a face-to-face assessment before the day of surgery but does not eliminate an evaluation of the patient's medical information in advance of surgery. In contrast, advance face-to-face preoperative assessment is more advisable for older patients, in whom multiple comorbidities, polypharmacy, and social problems are all more likely.[89] Early discharge planning is also important for older patients, to address environmental issues that can be improved to support recovery.[90]

In the United Kingdom, preoperative assessment is usually performed by nurses working closely to protocols and supported by anesthesiologists who provide advice and personally assess the more complex patients.[91] In the United States, anesthesiologist-led, protocol-driven preoperative assessment is often used for healthy patients having minor procedures. However, these preoperative evaluation clinics are frequently used in US hospitals, not just for ambulatory patients with more complex medical or surgical issues but also for the majority of inpatient surgery cases that are admitted on the morning of surgery. More complex patients have their anesthesia preassessment performed by an anesthesiologist. A comprehensive preoperative history and physical evaluation by a physician extender is often also provided in the preoperative assessment clinic for the surgeon. Using a physician extender to assist in preoperative evaluation maintains patient safety and satisfaction, promotes flexibility with scheduling of providers, and increases staff satisfaction.[92] Appropriately trained nurses were just as effective as trainee medical staff in detecting information likely to influence subsequent patient management, but they ordered significantly fewer unnecessary tests.[93]

Patients generally rate their preoperative assessment clinic experience very favorably, with their greatest concerns relating to waiting times.[94] Scheduling appointments of approximately twice as long for patients of ASA physical status grades III and IV than for those of grades I and II has been shown to reduce backlogs and maximum waiting times for preoperative evaluation to an acceptable level of about 10 minutes.[95]

PREOPERATIVE INVESTIGATION

The history and physical examination remain key elements of preoperative risk assessment, despite the availability of more sophisticated technologies.[76] In fact, most useful information can be obtained from the history, supplemented by simple observation of the patient.[96] Basic physical examination, such as routine chest auscultation, is often considered unhelpful in adult ambulatory surgery patients,[85,97] because findings that are unaccompanied by symptoms or functional limitation do not alter management. Although aortic stenosis may remain asymptomatic until it is quite severe, chest auscultation may be unreliable in its detection. In one high-risk population, 31% of patients without a detectable murmur nevertheless had some degree of aortic stenosis that was moderate or severe in 10% of cases,[98] whereas 31% of patients with a suggestive murmur did not have aortic stenosis on echocardiography. Ten patients with severe aortic stenosis (valve area 1 cm^2 or less, gradient 35-58 mm Hg) tolerated an unmodified anesthesia regimen for electroconvulsive therapy on 144 occasions without problems,[99] suggesting that ambulatory surgical patients with undiagnosed aortic stenosis may not inevitably be at excessive risk, when combined with appropriate procedure selection.

It is recognized that routine laboratory investigations are unhelpful because they may generate false-positive results or do not alter subsequent management.[100] In addition, such tests increase costs, are unpleasant and time-consuming for patients, and may lead to repeat testing with even further expense and delays. Consequently, many authorities recommend selective testing, based on indications from the patient's clinical evaluation and demographics.[101,102]

Although comorbidities become more prevalent with age, additional preoperative testing for older patients may still be unnecessary. In patients 70 years of age or older, routine preoperative blood test results were not predictive of postoperative complications.[103] While preoperative electrocardiograms of patients over 50 years of age detected abnormalities, such as bundle branch blocks, predictive of postoperative myocardial infarction, the recordings did not provide additional predictive value to that obtained from the patient history.[104] The National Institute for Health and Care Excellence no longer advocates patient age be used as a criteria for routine preoperative testing and also recommends few, if any, tests for healthy patients undergoing minor or intermediate surgery.[102] One large pilot study demonstrated that the elimination of all preoperative testing resulted in no increase in adverse events in the perioperative period and did not alter the rate of unanticipated admission or readmission within 30 days compared to indicated testing.[105]

Patient Preparation

Preoperative assessment plays a fundamental role in preparing patients for their ambulatory surgery experience. This may include ensuring appropriate social support is in place, checking that preexisting conditions are optimally treated, and providing information.

PROVISION OF INFORMATION

Patients need to be informed about what will happen on the day of surgery, because a well-prepared patient is likely to be more relaxed and more satisfied with the service provided.[85] A well-informed patient is also more likely to comply with important instructions and protocols, such as fasting intervals and management of regular medications. Many patients are disproportionately worried about highly unlikely outcomes, such as death and awareness,[106] yet somewhat less concerned about more common consequences such as nausea, vomiting, and postoperative discomfort. The preoperative discussion should help to allay the anxiety associated with unlikely risks. It was found that a specially designed website with text, animation, and video significantly increased patients' knowledge about anesthesia when compared with a combination of verbal and written information.[107]

Patients should be given specific information, preferably supplemented in writing, about how to manage their usual medications in the preoperative period. Some drugs (e.g., warfarin) should be stopped several days before surgery[78] and some hypoglycemic agents omitted before surgery.[108,109] However, other important medications should not be omitted.[73,74,80]

Information about medications should include over-the-counter and herbal products, which are commonly used but often regarded by patients as harmless and safe.[110] Despite some serious consequences and interactions associated with herbal medications,[111] not all practices specifically ask and advise patients about these products on a routine basis. (see also Chapter 33).[112]

PREOPERATIVE FASTING

Almost universal agreement now exists that the safe fasting interval for clear liquids is no more than 2 hours, in contrast to 6 hours for light meals.[113,114] These fasting intervals result in safe gastric volumes even in obese adults,[115] children,[116] and patients with diabetes and gastrointestinal (GI) reflux.[114] Indeed, a 2-hour interval is probably conservative, given that the stomach empties clear fluids exponentially, with a half-time of approximately 10 minutes.[117]

Despite guidelines based on decades of research, implementation remains poor, with many patients fasting for excessive periods and experiencing significant discomfort.[118-120] Rather than focusing on a minimum fasting time, patients should be encouraged to keep drinking until the latest time necessary for safety to reduce preoperative dehydration and its associated consequences.[114] In practice, this may mean asking patients to have a drink just before they leave home or even providing a drink on arrival if surgery is still more than 2 hours away. Advising patients to drink on the morning of surgery also makes it easier for them to take their medications. Milk added to tea or coffee does not appear to delay gastric emptying[121-123] and, in the United Kingdom, may provide more palatable choices of preoperative beverage. The US practice is for clear fluids only. Recently, it has been shown that allowing patients unrestricted access to water right up until they were called to the operating room significantly reduced the incidence of postoperative nausea and vomiting (PONV) without increasing the occurrence of clinically-significant pulmonary aspiration.[124] Practices such as chewing gum before surgery also may not be harmful. No consistent evidence exists of a clinically important increase in gastric volume associated with gum chewing in adults,[114,125] while in children it may promote gastric emptying and could also serve as a useful route for premedication.[126]

Besides feelings of thirst and hunger, excessive fasting also results in hypoglycemia in significant numbers of patients, with 14% of fasted healthy female ambulatory surgical patients having an admission blood glucose value of 45 mg/dL (2.5 mmol/L) or less.[127] Preoperative oral carbohydrates have been shown to improve subjective well-being, reduce thirst and hunger, and reduce postoperative insulin resistance, although convincing evidence of reduced length of stay is lacking,[114] at least for shorter procedures.[128]

PREMEDICATION

Premedication traditionally refers to the administration of medications to relieve anxiety before surgery. However, the term encompasses any medication given in the preoperative period and therefore includes prophylactic analgesia and antiemesis agents, as well as drugs used to promote gastric emptying or counteract acid secretions.

Management of Anxiety

The use of anxiolytic premedication is now uncommon in ambulatory anesthesia,[129,130] probably because of concerns that these medications will delay recovery. In fact, one meta-analysis found no evidence that anxiolytic premedication delayed the discharge of ambulatory patients, although impaired performance in some tests of psychomotor function was found and the authors questioned the relevance of some of the older studies to modern ambulatory practice now that short-acting anesthetics are the norm.[131]

Anxiety is nevertheless common in ambulatory surgery patients,[129] with up to twothirds showing symptoms. A preoperative consultation more than 2 weeks before surgery can reduce patient anxiety and improve satisfaction, especially if the anesthesiologist was perceived as empathic.[132] Patient satisfaction was further improved when their intraoperative care was provided by the same anesthesiologist who performed the preoperative consultation.[132]

Anxiolytic Premedication

Given that anxiety was commonly reported, doubtless some patients will benefit from anxiolytic premedication, but what is the optimal regimen? Oral midazolam provided more anxiolysis than temazepam but also produced more sedation and amnesia, resulted in more oversedated patients, and delayed recovery.[133] Oral alprazolam produced comparable anxiety reduction to midazolam without causing amnesia,[134] but it also caused greater impairment of psychomotor function in the early postoperative period. Neither anxiolytic premedication delayed clinical recovery, but this may be a relatively crude assessment tool, because recovery primarily depends on other factors. Intravenous midazolam given shortly before induction of anesthesia reduced both anxiety and postoperative nausea.[135] Such relatively late administration will not reduce anxiety while the patient waits preoperatively, but may be useful in a patient who needs to have an uncomfortable procedure before surgery, such as mammographic needle localization, in which satisfaction with both the procedure and subsequent breast biopsy was improved.[136]

Premedication is more commonly used in children. In one investigation, premedication with oral midazolam 0.2 mg/kg reduced emergence agitation associated with sevoflurane anesthesia without significant delay in recovery,[137] and doses up to 0.5 mg/kg did not delay recovery.[138] However, other patients have experienced delayed recovery at this dose[139,140] while not always having a reduction in anxiety.[140] The less stringent recovery endpoints needed for children compared with the independent functioning needed for adults should be kept in mind. Premedication with oral midazolam may itself provoke anxiety in children, but giving the child a small toy to play with first has been shown to be effective in reducing this anxiety.[141] Unfortunately, the effect of the toy as an alternative to midazolam was not evaluated. Play therapy and distraction can be more effective than midazolam in reducing anxiety in children, although this may require an elaborate approach.[142] A preoperative educational program portrayed as a “Saturday morning club” also reduced anxiety,[143] although the authors questioned whether the benefits achieved were worth the time and resources required. A simpler and highly effective approach is to allow children to watch age-appropriate video clips or movies during anesthetic induction with intravenous (South Korea) or inhaled (Canada) techniques.[144,145] A preoperative educational DVD also encouraged more positive parental involvement during the recovery period and reduced children’s postoperative pain.[146]

Because of variable efficacy and the potential for delayed recovery, alternatives to benzodiazepine premedication have been sought. In children, oral transmucosal fentanyl reduced preoperative anxiety and postoperative agitation, but a high incidence of predictable side effects, such as PONV and delayed discharge, limited its usefulness.[147] Selective α_2-adrenergic agonists have potentially useful sedative and analgesic effects, yet despite years of study they still have no clearly defined role in ambulatory surgery in which their advantages outweigh the risks for adverse events.[148] Clonidine is commonly used in pediatric practice, particularly to reduce agitation during emergence,[149] but the promising results of clinical trials do not always translate well into routine clinical practice and its effects on induction anxiety are less persuasive.[150]

Analgesic Premedication

Ambulatory patients are commonly premedicated with prophylactic oral analgesia in the expectation of achieving analgesic levels in the early postoperative period. Because the duration of action of acetaminophen (paracetamol) is relatively short (4-6 hours), it is unlikely to provide worthwhile postoperative analgesia, other than for an extremely short procedure. When patients received oral acetaminophen 1 g an hour before arthroscopic knee surgery, barely a third had plasma levels in the therapeutic analgesic range 30 minutes after arriving in recovery, whereas therapeutic levels were consistently achieved with intraoperative intravenous administration.[151]

The nonsteroidal antiinflammatory drugs (NSAIDs) are consistently more effective as analgesic premedicants. Some evidence indicates that NSAIDs have a small preemptive analgesic effect (i.e., they achieve a superior effect if given before rather than after surgery),[152,153] although one of the studies most strongly supporting this conclusion has been called into question.[154] Preoperative parecoxib followed by postoperative valdecoxib significantly reduced the opioid analgesic requirements and the incidence of opioid-related adverse effects after laparoscopic cholecystectomy.[155] As well as providing effective postoperative analgesia, etoricoxib premedication had an anesthetic-sparing effect during ambulatory ankle surgery.[156] Using a common dental model of postoperative pain, preoperative ibuprofen, diclofenac, and acetaminophen with codeine effectively controlled early postoperative pain.[157] Similarly, rofecoxib and ketorolac were equally effective in controlling postoperative pain after ambulatory surgery,[158] as were ibuprofen and ketorolac.[159] Sustained-release preparations of NSAIDs improve convenience by allowing earlier preoperative administration and a prolonged postoperative effect. Modified-release ibuprofen 1.6 g delayed the time until rescue analgesia was required after ambulatory third molar surgery in contrast to standard ibuprofen.[160] Several of these NSAIDs (and most cyclooxygenase-2 [COX-2] inhibitors are unavailable in the United States.

Selective COX-2 inhibitors are no more effective and offer few advantages over traditional NSAIDs in ambulatory surgery. Despite any inhibition of platelet function, the amount of blood loss seen during high-risk surgery, such as tonsillectomy, was not reduced in comparison with nonselective NSAIDs.[161,162] Nonetheless, COX-2 inhibitors are preferred by surgeons, so age-appropriate doses of oral celecoxib are used as premedication in the United States. Attempts to limit GI adverse effects, which are rare in acute use, has introduced other side effects and led to some drugs being withdrawn.[163] Selective COX-2 inhibitors may be better tolerated in patients with aspirin-sensitive asthma.[164]

Several other drugs have been evaluated for premedication. Controlled-release oxycodone did not improve pain scores or reduce opioid requirements within 24 hours of ambulatory gynecologic laparoscopic surgery.[165] In combination with ibuprofen, pregabalin 150 mg reduced median pain scores at rest and in motion after gynecologic laparoscopic surgery, but did not reduce postoperative analgesic requirements.[166] Perioperative administration of pregabalin 75 mg provided short-lived pain reduction after laparoscopic cholecystectomy, and a meta-analysis confirmed limited analgesic benefit, no reduction in opioid side effects, and increased sedation from its use.[167] Even less effective was pretreatment with magnesium sulfate 4 g, which had no impact on postoperative pain or analgesic consumption in patients undergoing ambulatory ilioinguinal hernia repair or varicose vein surgery.[168]

Prophylactic Antiemetics

Patients at moderate-to-frequent risk for PONV should receive prophylactic antiemetics. Preoperative steroids can provide both analgesic and antiemetic prophylaxis. Some investigators have given dexamethasone as premedication,[169,170] but it is more usually given after induction of anesthesia to reduce administration side effects.

Antacid and Gastrokinetic Premedication

The incidence of aspiration of gastric contents is infrequent in fasted elective surgical patients. Despite improvements in several surrogate measures, insufficient evidence exists of clinical benefit (i.e., a reduction in morbidity or mortality from aspiration) to recommend the routine use of antacids, metoclopramide, H_2-receptor antagonists, or proton pump inhibitors before elective ambulatory surgery.[113,114] Patients who are receiving these medications chronically should take them before surgery. Patients who regularly suffer from significant acid reflux in the fasted state will also benefit from the head-up tilt position during induction of anesthesia. This approach also may be useful in the supermorbidly obese patient undergoing bariatric surgery, in whom the use of prophylactic proton pump inhibitors and sodium citrate may be considered.[51]

Anesthetic Techniques

CHOICE OF TECHNIQUE

Ambulatory surgery requires the same basic standards as inpatient surgery in terms of facilities, staffing, and provision of equipment for delivery of anesthetic drugs, monitoring, and resuscitation. Quality, safety, efficiency, and the cost of drugs and equipment are all important considerations in choosing an anesthetic technique for ambulatory surgery. The choice of specific anesthetic drugs or techniques should enable appropriate and controllable intraoperative conditions followed by rapid recovery with minimal side effects and a prompt return to normal psychomotor activity. Achieving these aims also requires careful attention to the details of analgesia, antiemesis, and fluid management, and requires experienced staff to deliver a high-quality, efficient, and cost-effective service.

No single ideal anesthetic drug or technique for ambulatory surgery exists, and the choice depends on both surgical and patient factors. General anesthesia commonly remains the most popular technique with both patients and surgeons, in some cases despite clear benefits of local or regional anesthetic techniques.[171] Spinal anesthesia can be useful for lower extremity and perineal procedures, but must be modified for use in the ambulatory setting by the use of low-dose techniques[172,173] or short-acting drugs[174] to prevent delays in discharge because of residual motor or sympathetic block. Infiltration of local anesthesia, peripheral nerve blocks, or both facilitate the recovery process by reducing postoperative pain and minimizing the need for opioid analgesics after general anesthesia and should be used whenever possible. Many ambulatory procedures also can be performed using local anesthetic techniques, supplemented, if necessary, with sedatives or analgesic drugs, or both.

GENERAL ANESTHESIA

General anesthesia remains a popular choice with patients, surgeons, and anesthesia providers. Induction of general anesthesia is typically achieved with a rapid and short-acting intravenous anesthetic, although inhaled induction is often used in children and needle-phobic adults. Intravenous drugs are also popular for maintenance of anesthesia, especially where the availability of target-controlled infusion (TCI) systems simplifies delivery,[175] but the use of short-acting inhaled anesthetics, usually without nitrous oxide (N_2O), is more common due to greater ease of administration and lower risk of intraoperative awareness. No single anesthetic technique is clearly superior for ambulatory surgery. Other factors, such as the experience of the anesthesiologist, the use of adjuvant drugs, and the art of anesthesia, are still important to deliver the best quality care.[176]

INTRAVENOUS ANESTHESIA

Methohexital is of little more than historical interest while the long duration of thiopental means it has little or no role in ambulatory anesthesia. The same applies to benzodiazepines and ketamine when used at the doses needed to induce general anesthesia. Etomidate is associated with myoclonus, pain on injection, and a high incidence of PONV. Although reformulation of etomidate in a lipid solvent can reduce some of these disadvantages,[177] persisting concerns about suppression of adrenal steroidogenesis[178] have curtailed its use. The search for new and improved intravenous anesthetic drugs has seen several promising compounds evaluated,[179,180] but no really novel anesthetics have yet become available[181] and propofol remains the most practical intravenous anesthetic for ambulatory anesthesia.

Propofol

Propofol has many of the properties of an ideal anesthetic induction drug and is popular because it rapidly and smoothly induces anesthesia without airway irritation and results in a rapid recovery with an infrequent incidence of early PONV[182] and a clear head. Propofol has some disadvantages, however, including pain on injection, involuntary movements, transient apnea, and hypotension after induction of anesthesia. Numerous strategies have been proposed to reduce pain on injection, of which the use of a large antecubital vein or pretreatment with lidocaine in conjunction with venous occlusion are the most effective,[183] and superior to altering the formulation of propofol.[184]

Some of the adverse effects of propofol can be minimized by reducing the propofol dose by coinduction with adjuvant drugs, the most common being midazolam. Pretreatment with midazolam 0.1 mg/kg allowed anesthesia to be induced with a decreased propofol dose and also attenuated the resultant hemodynamic changes.[185] A substantial decrease in the propofol dose can be achieved even when midazolam is administered up to 10 minutes before induction of anesthesia, a technique that also can make the induction experience for the patient more pleasant.[186] However, this approach may delay recovery. Midazolam 0.03 mg/kg halved the required propofol dose but significantly impaired psychomotor recovery, even though awakening times were not delayed.[187] Coinduction with short-acting opioids, such as alfentanil, can improve the quality of induction and ease of laryngeal mask airway (LMA) insertion, but at the expense of an increased incidence of hypotension and prolonged apnea.[188] Similarly, fentanyl reduced propofol dose and improved conditions for LMA insertion, but also prolonged respiratory depression.[189] Furthermore, the use of 1 μg/kg[190] or fixed doses of 75 μg[191] to 100 μg[192] of perioperative fentanyl increase the incidence of PONV. Giving an initial bolus of 30 mg of propofol reduced the total propofol induction dose to a degree similar to that achieved by 2 mg of midazolam.[193] This technique, which has been termed propofol autocoinduction,[194] can reduce propofol dose and hypotension to a degree comparable to that with midazolam pretreatment but without delaying recovery. Following the concepts of opioid minimization and enhanced recovery after surgery, propofol coinduction can also be performed with intravenous lidocaine.

The pharmacokinetics of propofol allow it to be used as a variable rate infusion to maintain anesthesia, either in association with N_2O or combined with alfentanil or remifentanil as total intravenous anesthesia (TIVA). Recovery after anesthesia maintained with propofol is typically no faster compared to volatile anesthetics after an induction dose of propofol,[182] and initial awakening may be delayed compared to that with the shorter-acting inhaled anethetics.[195] These differences in emergence times are no more than 2 to 3 minutes[196] and so not of clinical significance. Recovery to home readiness may occur up to 15 minutes sooner after propofol than isoflurane but is no faster than sevoflurane or desflurane. There are conflicting reports on whether propofol may be more[197] or less[198] likely than inhaled anesthetics to impair cognitive dysfunction after ambulatory anesthesia in older patients. One consistent feature of propofol anesthesia is a less frequent incidence of early PONV in contrast to the use of inhaled anesthetics.[182,196,199] However, even this benefit has been described as of doubtful clinical relevance, except when the baseline incidence of PONV is very high.[199] The reduction in PONV achieved by TIVA, specifically the use of propofol and the omission of N_2O, was similar to that produced by the use of single-drug antiemetic prophylaxis.[200] Furthermore, any reduction in PONV appears to be confined to the early recovery phase as propofol use for ambulatory surgery does not alter the rate of unanticipated hospital admission and increases the incidence of nausea following discharge, probably because long-acting antiemetics (e.g., dexamethasone) had not been given.[201]

Outside of the United States, delivery of propofol is increasingly performed by TCI, which makes the delivery of propofol easier, with fewer interventions required by the anesthesiologist, in contrast to manual infusions.[202] However, it does not improve the quality of anesthesia, shorten recovery time, or reduce adverse events,[202,203] although the quality of trials performed to date is poor. A further issue is that TCI systems calculate the predicted plasma propofol concentration and considerable variation exists between this and the actual measured value.[203] Further sources of error are introduced when the effect site, rather than the plasma concentration, is targeted.[204] Currently two different pharmacokinetic models are in common use, both derived from healthy subjects. The choice of model may make relatively little difference in the young, fit patient, but performance differs considerably in older patients[204] and neither model is reliable in the morbidly obese.[204,205] Even newer pharmacokinetic models developed specifically with data from obese patients have a tendency to underestimate plasma propofol concentrations.[206]

INHALED ANESTHETICS

Volatile anesthetics remain the most popular choice for the maintenance of ambulatory anesthesia because of their ease of administration, controllability, and rapid emergence. Halothane and enflurane are now of historical interest only, and use of isoflurane has declined considerably as less-soluble, shorter-acting drugs have become available.

Sevoflurane

The low solubility and minimal airway irritation of sevoflurane make it a readily controllable, short-acting anesthetic for ambulatory surgery.[195] In contrast to isoflurane, sevoflurane resulted in significantly earlier awakening and orientation, caused less postoperative drowsiness, and facilitated earlier discharge by an average of 25 minutes.[196] Compared to propofol, orientation occurred earlier but the time to home readiness was similar.[196] The lack of airway irritation with sevoflurane means that rapid increases in inspired concentration are well tolerated,[207] facilitating control of anesthetic depth. This is in contrast to the cough reflex[208] and transient increases in heart rate and blood pressure, which sudden changes in isoflurane or desflurane concentration may provoke.[209]

Lack of airway irritation makes sevoflurane almost ideal for inhaled induction, which may be especially desirable in children and needle-phobic adults.[195] An 8% bolus induction of sevoflurane in adult patients can be faster than with propofol, with a similar rate of different side effects.[210] Sevoflurane induction also caused significantly less depression of mean arterial pressure than propofol in older patients and was equally as well accepted as an induction choice.[211] Using sevoflurane for volatile induction and maintenance of anesthesia (VIMA) has several benefits for ambulatory patients, but is associated with a greater incidence of PONV than when propofol is used for induction, maintenance, or both, of anesthesia.[195] This appears to be in part due to coadministered opioids, which are rarely needed with VIMA, because omitting the opioids minimizes the problem.[190,210,212] In children, the rapid emergence from sevoflurane (and desflurane) anesthesia is associated with a high incidence of emergence delirium, especially if inadequate measures are in place to control postoperative pain.[213] Numerous strategies have been evaluated to reduce emergence delirium. Midazolam premedication is ineffective, but supplemental use of fentanyl 1 μg/kg, propofol, ketamine, and α_2-adrenergic agonists all reduce agitation to some degree.[149] Although emergence delirium is undesirable, it is not associated with any long-term consequences and does not delay recovery room discharge.[214] There is insufficient evidence of adequate quality to show whether propofol TIVA reduces the risk of behavioral disturbances (or PONV) compared with inhaled anesthesia.[215]

Desflurane

With its low blood solubility, desflurane should be an ideal anesthetic for ambulatory anesthesia. However, meta-analysis of 25 randomized studies showed that patients receiving desflurane followed commands, had their trachea extubated, and were oriented only 1.0 to 1.2 minutes earlier than those receiving sevoflurane for up to 3.1 hours.[216] No differences were found in recovery room stay[217] or incidence of PONV.[216] Concerns about the more frequent incidence of airway irritation with desflurane may limit the rapidity with which anesthetic depth can be altered,[209] although relatively few problems were encountered in patients spontaneously breathing desflurane through an LMA when coadministered with fentanyl.[218,219] Although desflurane has lower fat solubility than sevoflurane, the rate of diffusion into the fat compartment is extremely slow with either inhaled anesthetic; therefore, lower fat solubility does not make the case for use of desflurane as the ideal agent for morbidly obese patients unless procedure length is very long. In practice, some studies of ambulatory surgery in the morbidly obese have found more rapid recovery after desflurane than sevoflurane,[220] whereas others found emergence and recovery to be similar with either drug.[221]

ANESTHETIC ADJUVANTS

Some adjuvant drugs are frequently administered to supplement the effects of general anesthesia and in an effort to reduce adverse effects.

Nitrous Oxide

Although N_2O is by far the oldest anesthetic drug still in use, its role is regularly questioned. N_2O is weakly emetogenic, yet its omission only significantly decreases vomiting when the baseline incidence is high and has no effect on nausea or the complete control of PONV.[222] Others have found the effects of omitting N_2O to be “modest.”[223] This may be because the alternatives, specifically a higher inhaled anesthetic concentration or the use of supplemental opioids, also induce PONV. The effect of N_2O on PONV appears to be time-dependent. There was no clinically significant effect from at least an hour’s exposure,[224] allowing N_2O to retain a place in modern ambulatory anesthesia where its use also improves the quality, speed, and safety of induction of anesthesia, facilitates faster recovery, and reduces overall costs.[225]

Opioid Analgesics

The indiscriminate use of opioid analgesics should be discouraged in ambulatory surgery to avoid PONV and unplanned admission.[226,227] Although long-lasting drugs such as morphine are especially detrimental, even the ultra–short-acting opioid remifentanil resulted in a 35% incidence of PONV when used with desflurane and multimodal prophylaxis, compared with only 4% when all opioids were avoided.[228] For minor to intermediate ambulatory surgery procedures, the routine administration of as little as 1 μg/kg of fentanyl serves only to increase the incidence of PONV,[229] and its omission does not worsen postoperative pain, provided prophylactic analgesia is ensured with local anesthetic infiltration and preoperative NSAIDs.[190] However, small doses of fentanyl may be useful to provide additional analgesia toward the end of more painful procedures.

Opioids are an essential component of TIVA, but the antiemetic effect of propofol minimizes the incidence of PONV in contrast to the use of the same opioid with inhaled anesthetics.[230] Compared to alfentanil, remifentanil provides more effective suppression of intraoperative responses without prolonging awakening.[231] However, there is increasing evidence emerging that remifentanil is associated with both acute opioid tolerance and opioid-induced hyperalgesia,[232,233] which can increase postoperative analgesic requirements. This hyperalgesia is partially reduced by NSAIDs[233] and by concurrent N_2O administration,[234] although remifentanil is usually used as an N_2O replacement.

Nonopioid Analgesia

For longer or more invasive procedures, intravenous acetaminophen given toward the end of surgery also can have a beneficial effect,[151,235] comparable to that of the opioid tramadol.[236] For shorter procedures, acetaminophen can be given orally before the anesthetic, at much lower cost.

Cardiovascular Drugs

Although intraoperative hemodynamic disturbances are usually managed by increasing the primary anesthetic concentration, administering an opioid analgesic, or both, it may be more appropriate to treat these responses with cardiovascular drugs. Using an infusion of esmolol as an alternative to alfentanil to control heart rate reduced emergence times after arthroscopy,[237] and substituting esmolol for remifentanil reduced nausea after gynecologic laparoscopy.[228] Using a combination of esmolol and nicardipine to blunt increases in heart rate and arterial blood pressure, respectively, prevented the need for increases in inspired anesthetic concentration and consequently shortened emergence and recovery times.[238] Ambulatory patients who received esmolol intraoperatively for hemodynamic control also had significantly smaller requirements for postoperative opioid analgesia.[238,239] Administration of a continuous infusion of esmolol during laparoscopic gynecologic surgery reduced sevoflurane consumption by 18%, shortened recovery room stay, reduced postoperative pain scores, and reduced fentanyl requirements.[240] In a similar study, an esmolol infusion decreased intraoperative remifentanil requirements and again resulted in lower postoperative pain scores and halved the dose of rescue fentanyl.[241] Labetalol may be a cost-effective alternative to esmolol for longer cases, especially in older patients in whom it is less likely to cause inadvertent hypotension.[242]

Neuromuscular Blocking Drugs

Neuromuscular blocking drugs (NMBDs) may be used in ambulatory anesthesia to facilitate endotracheal intubation or to provide profound surgical relaxation. Although several of the available compounds are suitable, muscle pain after administration of succinylcholine and concerns about residual neuromuscular block from intermediate-duration NMBDs after brief procedures have fueled the search for alternatives. The search for a nondepolarizing equivalent to succinylcholine has been unsuccessful to date. The most promising candidate, rapacuronium, was withdrawn from clinical use because of a frequent incidence of severe bronchospasm, although other factors such as inconvenient administration, declining use of endotracheal intubation, and high costs also contributed to its lack of commercial success.[243] The search for a rapid-onset, short-acting nondepolarizing NMBD continues with investigation of several fumarate compounds, of which gantacurium was found to have rapid onset and brief duration, but was also associated with histamine release.[244] Subsequent attention has moved toward designing a molecule of intermediate duration, but which can be rapidly reversed at any time by administering L-cysteine.[244]

An alternative to short-acting NMBDs is terminating the neuromuscular blockade with sugammadex, which can rapidly and completely reverse rocuronium (or vecuronium) independent of the degree of residual neuromuscular block.[245] Sugammadex is very expensive compared to neostigmine, although in the United States the cost of neostigmine has risen dramatically. Currently no reliable evaluations have been done on the cost-effectiveness of sugammadex in routine clinical practice. Although improved recovery times resulting from the elimination of residual neuromuscular block by sugammadex may potentially be cost-effective, this depends on the productivity of staff during the time saved and would probably require major changes to the workflow for actual benefits to be realized.[245]

Endotracheal intubation also can be achieved without the use of NMBDs, thereby avoiding all of their adverse effects. This practice is most common in children, for procedures in which airway protection, but not prolonged muscle relaxation, is required. The optimum technique depends on personal experience and preference, but most commonly involves deep sevoflurane anesthesia[246] or propofol supplemented by remifentanil or alfentanil.[247] For adults, a dose of remifentanil 3 μg/kg with propofol 2 mg/kg is recommended,[248] but satisfactory conditions can be obtained with remifentanil 2 μg/kg, thereby reducing the side effects of bradycardia and hypotension.

AIRWAY MANAGEMENT

Many ambulatory surgical patients can be managed with an LMA, which results in a significantly less frequent incidence of sore throat, hoarseness, coughing, and laryngospasm compared to inserting a tracheal tube.[249] The LMA can occasionally cause pressure trauma to a variety of cranial nerves, in particular the recurrent laryngeal nerve, whereas hoarseness and vocal cord injuries are common after the use of endotracheal intubation during short-term anesthesia.[250] The LMA is relatively easy to insert with patients in the prone position,[251] making it a simple way of managing procedures such as pilonidal sinus repair or surgery to the short saphenous vein.

Traditionally, endotracheal intubation has been advocated for laparoscopic procedures and surgery in obese patients, but further development of the LMA and more confidence in its use may be changing this. The ProSeal LMA (Teleflex, Morrisville, NC) has been modified to provide increased seal pressure, reduce gastric inflation, provide for gastric drainage, and, therefore, allow potentially better protection against aspiration of gastric contents while maintaining similar insertion characteristics.[252] At least one large consecutive series by an experienced user appears to support these benefits in routine clinical practice, without the constraints of a clinical trial.[253] During laparoscopic cholecystectomy, the ProSeal LMA provided adequate pulmonary ventilation without gastric distention in nonobese patients, although it was somewhat less effective than endotracheal intubation in the obese.[254] A recent review found that second-generation LMAs (with higher seal pressures and a drain channel) achieve adequate ventilation during laparoscopic cholecystectomy with a very low incidence of regurgitation and aspiration, but still cannot yet be regarded as completely safe.[255]

Provided safety can be ensured, avoiding endotracheal intubation by using the ProSeal LMA for laparoscopic surgery appears to offer considerable advantages, including considerably smoother emergence with significantly less coughing.[254,256] In laparoscopic gynecologic procedures, the ProSeal LMA was associated with lower pain scores at 2 and 6 hours, with reduced analgesic requirements and less nausea at the same times.[257] Similarly, in females undergoing gynecologic laparoscopic or breast surgery, it reduced the absolute risk for PONV by 40% and also reduced sore throats, analgesic requirements, and recovery room stay.[258] During laparoscopic gastric banding, the ProSeal LMA reduced the intraoperative stress response and also shortened recovery room stay and hospital discharge.[259]

Since the expiration of LMA patents, many manufacturers have introduced similar designs, often using different materials to produce a low-cost disposable product. Often little or no data are available on the effectiveness or safety of these generic products.[260] Furthermore, the success of the LMA led to the development of many new supraglottic airways of myriad designs. Some of these may offer advantages in ambulatory surgery,[261] although there is often little or no comparative data with the LMA. Anesthesiologists should therefore be wary of the claims made for new airway devices until they have been adequately evaluated.[262]

One supraglottic airway that has been extensively evaluated is the i-gel (Intersurgical, East Syracuse, New York), which has a contoured noninflating cuff and gastric drainage channel. The i-gel is faster to insert and results in less sore throat than the LMA with a seal pressure intermediate between first- and second-generation LMAs.[263]

REGIONAL ANESTHESIA

Spinal Anesthesia

The use of spinal anesthesia makes ambulatory surgery accessible to some patients for whom the risks of general anesthesia are excessive. It also increases patient choice, allows participation in intraoperative decision making (e.g., in sports injuries), and provides beneficial postoperative analgesia. Various ambulatory surgical procedures, such as transurethral prostatectomy, female incontinence surgery, and ankle and foot surgery, are well suited to spinal anesthesia.

The ready availability of fine-gauge, pencil-point spinal needles has reduced the incidence of significant postdural puncture headache to 0.5% to 1%.[264] The main challenge now is to prevent prolonged motor block or impairment of joint position sense from delaying discharge. Although lidocaine has an appropriate duration for ambulatory surgery, its use in spinal anesthesia has virtually ceased as a result of a high incidence of transient neurologic syndrome (TNS).[265] Until fairly recently, bupivacaine was the most obvious alternative, being devoid of TNS, but causing unacceptable delays in home discharge if used in standard doses.

For its acceptance in ambulatory surgery, bupivacaine spinal anesthesia needs to be “modified.”[266] Reducing the dose of bupivacaine shortens recovery, whereas the use of patient positioning or the addition of adjuvants, such as fentanyl, ensures adequate analgesia for surgery. These techniques can be summarized as selective spinal anesthesia (SSA), defined as “the practice of employing minimal doses of intrathecal agents so that only the nerve roots supplying a specific area and only the modalities that require to be anaesthetized are affected.”[267] SSA provides analgesia suitable for surgery, and light touch, temperature, proprioception, motor, and sympathetic function are all preserved.[267] This results in remarkable cardiovascular stability but can make the block difficult to test, and patient cooperation is important to the success of this technique.

A variety of SSA regimens have been described,[173] which typically permit discharge within a little over 3 hours after surgery.[268] The addition of fentanyl marginally delays recovery and is associated with pruritus[268] (although most cases do not require treatment), but also reduces postoperative pain and analgesic requirements.[269] For unilateral knee arthroscopy, 4 to 5 mg of hyperbaric bupivacaine appears to be sufficient without adjuvants, provided the patient is kept in the lateral position.[269] Clonidine has also been used to supplement low-dose spinal anesthesia, but it may prolong motor block, exacerbate hypotension, and delay voiding.[148]

Spinal anesthesia may contribute to postoperative urinary retention. This is uncommon in low-risk patients, but may be more likely in older patients, with certain procedures and when more than 7 mg of bupivacaine is used.[266] The risk for urinary retention is particularly high after inguinal hernia surgery,[270] but simple infiltration anesthesia is often sufficient for this procedure and may be a more appropriate choice.[171,271]

New Drugs for Ambulatory Spinal Anesthesia

With the increasing popularity of ambulatory spinal anesthesia, some older local anesthetics have been reevaluated and, in some countries, marketed for spinal use.[174] Of these, prilocaine and 2-chloroprocaine have been evaluated the most.[272,273] Hyperbaric prilocaine has a faster onset and shorter duration than the plain preparation,[272] with patients receiving 40 mg of 2% hyperbaric prilocaine being home ready in 208 ± 68 minutes.[274] This is comparable to discharge times reported with low-dose bupivacaine plus fentanyl,[268] although 13% of the patients receiving hyperbaric prilocaine required supplementation for inadequate analgesia toward the end of surgery, which was scheduled to last for less than an hour.[274] Doses of 40 to 60 mg achieve analgesia of about 90 minutes duration for lower abdominal or limb procedures, while 10 to 30 mg is adequate for perineal surgery of up to 40 minutes, with home discharge usually achievable within 4 hours.[272] The duration of 2-chloroprocaine is even shorter, with recovery being significantly faster than that of low-dose bupivacaine[275] or articaine[174] and comparable to that of lidocaine.[276] The addition of fentanyl appears to extend the block duration of both 2-chloroprocaine[273] and prilocaine[272] with little delay in recovery in either case. TNS is much less common than with lidocaine, but still occasionally reported after both prilocaine[277] and 2-chloroprocaine.[273]

Ambulatory spinal anesthesia that relies on short-acting local anesthetics should be compared with the cardiovascular stability of SSA. Prilocaine 20 mg combined with 20 µg fentanyl was associated with a lower incidence of clinically significant hypotension compared with bupivacaine 7.5 mg with fentanyl 20 µg.[278] However, the doses of bupivacaine and fentanyl used in both groups were somewhat higher than usual.

Epidural Anesthesia

Epidural analgesia is seldom used in adult ambulatory anesthesia. Although it allows the block duration to be extended by using a catheter technique, this is offset by the time required in establishing the block and less certainty of success, as well as the risk for inadvertent intravascular injection or dural puncture. In knee arthroscopy, recovery after 15 to 20 mL of epidural

TABLE 72.3 Some Common Upper and Lower Extremity Blocks Used for Adult Ambulatory Surgery

Type of Block	Type of Surgery	Bolus Dose (Perioperative)	Continuous Infusion	Patient-controlled regional analgesia (PCRA)
Interscalene block	Surgery around the shoulder	Bupivacaine/*levo*-bupivacaine 0.25-0.5%, 20-40 mL *or* Ropivacaine 0.5%, 20-40 mL	Ropivacaine 0.2% 5 mL/h	Ropivacaine 0.2% 5 mL/h
Supra- or infra-clavicular block	Surgery around elbow, wrist, and hand	Bupivacaine/*levo*-bupivacaine 0.25-0.5%, 20-40 mL *or* Ropivacaine 0.5%, 20-40 mL	Ropivacaine 0.2% 5 mL/h	Ropivacaine 0.2% 5 mL/h
Sciatic nerve block	Posterior cruciate ligament repair, foot and ankle surgery	Bupivacaine/*levo*-bupivacaine 0.25-0.5%, 20-40 mL *or* Ropivacaine 0.5%, 20-40 mL	Ropivacaine 0.2% 5 mL/h	Ropivacaine 0.2% 5 mL/h
Femoral nerve block	Knee arthroplasty, anterior cruciate ligament repair	Bupivacaine/*levo*-bupivacaine 0.25-0.5%, 20-40 mL *or* Ropivacaine 0.5%, 20-40 mL	Ropivacaine 0.1% 5 mL/h	Ropivacaine 0.1%, 10 mL with 60 min lock-out time
Paravertebral block (thoracic)	Breast surgery	Bupivacaine/*levo*-bupivacaine 0.25-0.5%, 20-40 mL *or* Ropivacaine 0.5%, 20-40 mL	Ropivacaine 0.2% 5 mL/h	Ropivacaine 0.2% 5 mL/h

Doses are approximations, with lower doses recommended when using ultrasound techniques. Depending on the type of surgery, multiple nerves may need to be blocked to get good postoperative pain relief. When using catheter techniques, disposable pumps with pre-filled local anesthetics may be given to the patient with suitable written and verbal instructions.

Reproduced from Gupta A, Smith I. Local and regional anaesthesia. In: Smith I, McWhinnie D, Jackson I, eds. *Day Case Surgery*. London: Oxford University Press; 2012:93–108. With permission.

3% 2-chloroprocaine was more rapid than spinal procaine with 20 μg fentanyl[279] and also had a decreased incidence of pruritus. Recovery after epidural 3% 2-chloroprocaine required fewer top-up injections and permitted discharge an hour sooner after ambulatory knee arthroscopy than with 1.5% epidural lidocaine.[280] However, the use of epidural 2-chloroprocaine has a more frequent incidence of back pain.[281]

In children, caudal epidural analgesia—for example, using levobupivacaine 0.5 to 1 mL/kg of 0.25%—is popular for postoperative pain relief.[64] The technique is most useful for bilateral surgery or other situations in which the maximum safe dose would not permit an adequate volume for wound infiltration. After circumcision, caudal analgesia was no better than parenteral or systemic analgesia or dorsal nerve block in reducing analgesic requirements, nausea, or vomiting.[282] However, motor block and leg weakness were significantly more common in boys receiving a caudal block. The addition of clonidine[283] or dexmedetomidine[284] augments caudal analgesia, but concerns remain about the frequency of sedative and hemodynamic side effects and the risk for neurotoxicity.[148,283]

Intravenous Regional Anesthesia

Intravenous regional anesthesia (IVRA) (Bier block) is a simple, reliable method of analgesia most commonly used in the upper limb, but sometimes also used effectively in the lower extremity.[285] In the United Kingdom and Europe, prilocaine is the preferred local anesthetic because of its high therapeutic index.[286] Lidocaine has also been used for many years,[285] and appears to be a safe alternative.[287] Ropivacaine has also been extensively evaluated for IVRA. Compared to lidocaine, 0.2% to 0.375% ropivacaine resulted in prolonged and improved postoperative analgesia.[288-290] However, compared to prilocaine, ropivacaine's onset was slower, no useful prolongation of postoperative analgesia occurred, and ropivacaine plasma concentrations were more than double those of prilocaine, despite a 60% lower dose.[286]

IVRA was a cost-effective alternative to general anesthesia for outpatient hand surgery, being equally rapid to administer and with faster recovery and fewer postoperative complications.[291] However, analgesia was inadequate in approximately 11% of cases, which required supplemental local anesthesia, repeat of the block, and even conversion to general anesthesia. IVRA was also cost effective, and quicker to perform, compared to brachial plexus block, but with a 4.4% failure rate due to tourniquet pain.[292]

A variety of adjuvants have been used in IVRA to decrease tourniquet pain, improve block quality, and prolong analgesia after cuff deflation.[293] Opioids are relatively ineffective and cause nausea, vomiting, and dizziness after tourniquet deflation,[293] but several NSAIDs have been shown to be beneficial. Lornoxicam[294] decreased tourniquet pain and improved postoperative analgesia and tenoxicam improved postoperative pain,[293] but the effects of ketorolac are unclear after most of the evidence showing its efficacy in IVRA was withdrawn.[154] Dexamethasone improved both block quality and postoperative analgesia.[295] Similar results have been observed with the α_2-adrenoceptor agonist dexmedetomidine,[296,297] whereas clonidine delayed tourniquet pain without improving postoperative analgesia.[298]

Other Local and Regional Anesthetic Techniques

A wide range of other regional anesthetic techniques can be used to facilitate ambulatory surgery or provide postoperative analgesia (Table 72.3).[299] The applicability of these techniques depends on the nature of the planned procedure, the patient, the preferences of the surgeon and anesthesiologist, as well as the skill and experience of the anesthesiologist performing the block. Benefits include excellent postoperative analgesia and reduced PONV, but this must be offset against pain and discomfort while performing the block, the difficulty of transitioning to satisfactory analgesia when the block wears off, and the risk for perioperative nerve injuries. Regional anesthesia may be contraindicated in patients with bleeding problems or those taking anticoagulants, as well as in patients with local infections. Regional anesthesia has a high failure rate in inexperienced hands, especially in the morbidly obese patient, although ultrasound guidance appears to improve the success rate of many blocks and can reduce pain during block placement.[300] While there is no conclusive evidence that ultrasound guidance reduces the incidence of peripheral nerve injury, it does appear to reduce local anesthetic systemic toxicity and lowers the incidence of hemidiaphragmatic paresis and pneumothorax associated with certain blocks.[301]

Simpler locoregional techniques may be more appropriate for some procedures. Intraarticular local anesthesia produces a moderate and relatively brief reduction in postoperative pain after arthroscopic knee surgery, but this is still considered to be of clinical significance in ambulatory surgery.[302] In many cases, simple wound infiltration may be as effective as central and proximal peripheral blocks and allows patients to mobilize more quickly.[303] Concerns about the possible risk for infection, or systemic toxicity resulting from large volumes of local anesthetic, appear unfounded in clinical practice.[303]

Infiltration anesthesia offers advantages for many ambulatory procedures and is the method of choice for inguinal hernia repair.[171] Several large series have confirmed excellent results with this highly cost-effective technique, with 79% of patients requiring oral analgesia for 7 days or less after surgery[304] and 91% of patients returning to normal activities within 5 days.[305] Repair under local anesthesia is not an independent factor for hernia recurrence, although this is influenced by the type of hernia and the level of surgical experience.[306] Infiltration anesthesia resulted in fewer medical and urological complications after groin hernia repair than either general or regional anesthesia.[271] If spinal anesthesia is chosen for groin hernia repair, the anesthesiologist should be aware of the increased risk for urinary retention and other medical complications, especially in older patients.[271]

The concept of simple wound infiltration has been further developed into local infiltration analgesia (LIA), used for major orthopedic ambulatory surgery. This multimodal technique was developed for the control of pain after inpatient knee and hip surgery in Australia by Kerr and Kohan.[307] Their technique used a mixture of 300 mg ropivacaine with 30 mg ketorolac and 1.5 mg epinephrine diluted to 150 to 200 mL with saline, infiltrated into all the tissue planes of the surgical field over approximately an hour as the operation progressed. A catheter was placed into the wound to permit later repeat dosing. In the original series of 325 patients, mainly undergoing elective hip resurfacing but including some primary hip and knee replacements, pain was well controlled (numerical pain score 0-3) without morphine in twothirds of patients, most of whom could walk with assistance 5 to 6 hours after surgery; 71% were discharged, walking independently after a single night stay (Fig. 72.2).[307] These promising results have been confirmed in a blinded, randomized trial in patients undergoing unicompartmental knee arthroplasty, where a similar LIA regimen significantly reduced pain and opioid consumption and decreased the median length of stay by 2 days, with 68% of patients discharged after a 1-night stay.[308] A recent review suggests that LIA is beneficial after knee surgery, even when combined with multimodal systemic analgesia, but adds little additional analgesia after hip surgery when a multimodal regimen is also used.[309]

A limitation of infiltration anesthesia in general is the relatively short duration of pain relief it provides, even with long-acting drugs such as bupivacaine. The encapsulation of bupivacaine into a biodegradable carrier offers the prospect of extended-duration local anesthesia, which has demonstrated significant analgesic effects for at least 96 hours in pilot studies.[310] Several potential problems need to be solved before widespread application, however, including ensuring that the large doses of local anesthetic contained within the carrier are not rapidly released, leading to toxicity, or that the encapsulating materials do not break down into harmful products.[311] One extended-duration preparation of bupivacaine, Exparel, which uses an established liposomal-based drug delivery system (Lipo Foam, Contour^{MD}), is currently approved by the US Food and Drug Administration (FDA). Early trial results report improved pain scores and reduced opioid analgesic consumption compared to plain bupivacaine during the first 24 to 48 hours or more after bunion surgery,[312] knee replacement,[313] and breast augmentation.[314] Myalgia was observed after administration of liposomal bupivacaine in six patients in one study,[314] but a 2-year follow up from the same group reported no long-term complications.[315] Several studies appear to support the efficacy and patient acceptability of liposomal bupivacaine after abdominal wall reconstruction, mastectomy, and mammoplasty, although the quality of comparative studies to date is poor.[316] However, systematic reviews suggest no improvement over conventional analgesia for shoulder arthroplasty[317] or bilateral knee surgery[318] and only marginal benefits of questionable clinical significance after unilateral knee surgery.[319] Catheter techniques also can extend the duration of effective local or regional analgesia, reducing pain scores, opioid-related side effects, and length of hospital stay, as well as improving patient satisfaction.[320]

Several naturally occurring alkaloid toxins, which may have the potential to provide longer lasting and safer local anesthesia, have been considered.[311] A preliminary study with neosaxitoxin, an extracellular sodium channel blocker, described superior analgesia compared to that with bupivacaine at 12 hours after laparoscopic cholecystectomy.[321] Subcutaneous injection of neosaxitoxin in combination with bupivacaine and epinephrine produced a five-fold increase in analgesic duration compared with bupivacaine alone, without an apparent increase in toxicity.[322]

SEDATION

Although some procedures may be performed with local or regional anesthesia alone, additional drugs are often required for anxiolysis, to provide additional analgesia and to attain suitable operating conditions by helping the patient lie still in an appropriate position. The level of sedation required varies with each therapeutic, diagnostic, or surgical procedure and must be individually adjusted to achieve a balance of patient comfort and safety.[323]

The ASA defines three levels of sedation according to the responsiveness of the patient.[324] With minimal sedation a degree of anxiolysis is reached, but the patient is normally responsive and has a clear airway. During moderate (conscious) sedation the patient is sleepier but responds purposefully to verbal or tactile stimuli. Spontaneous ventilation

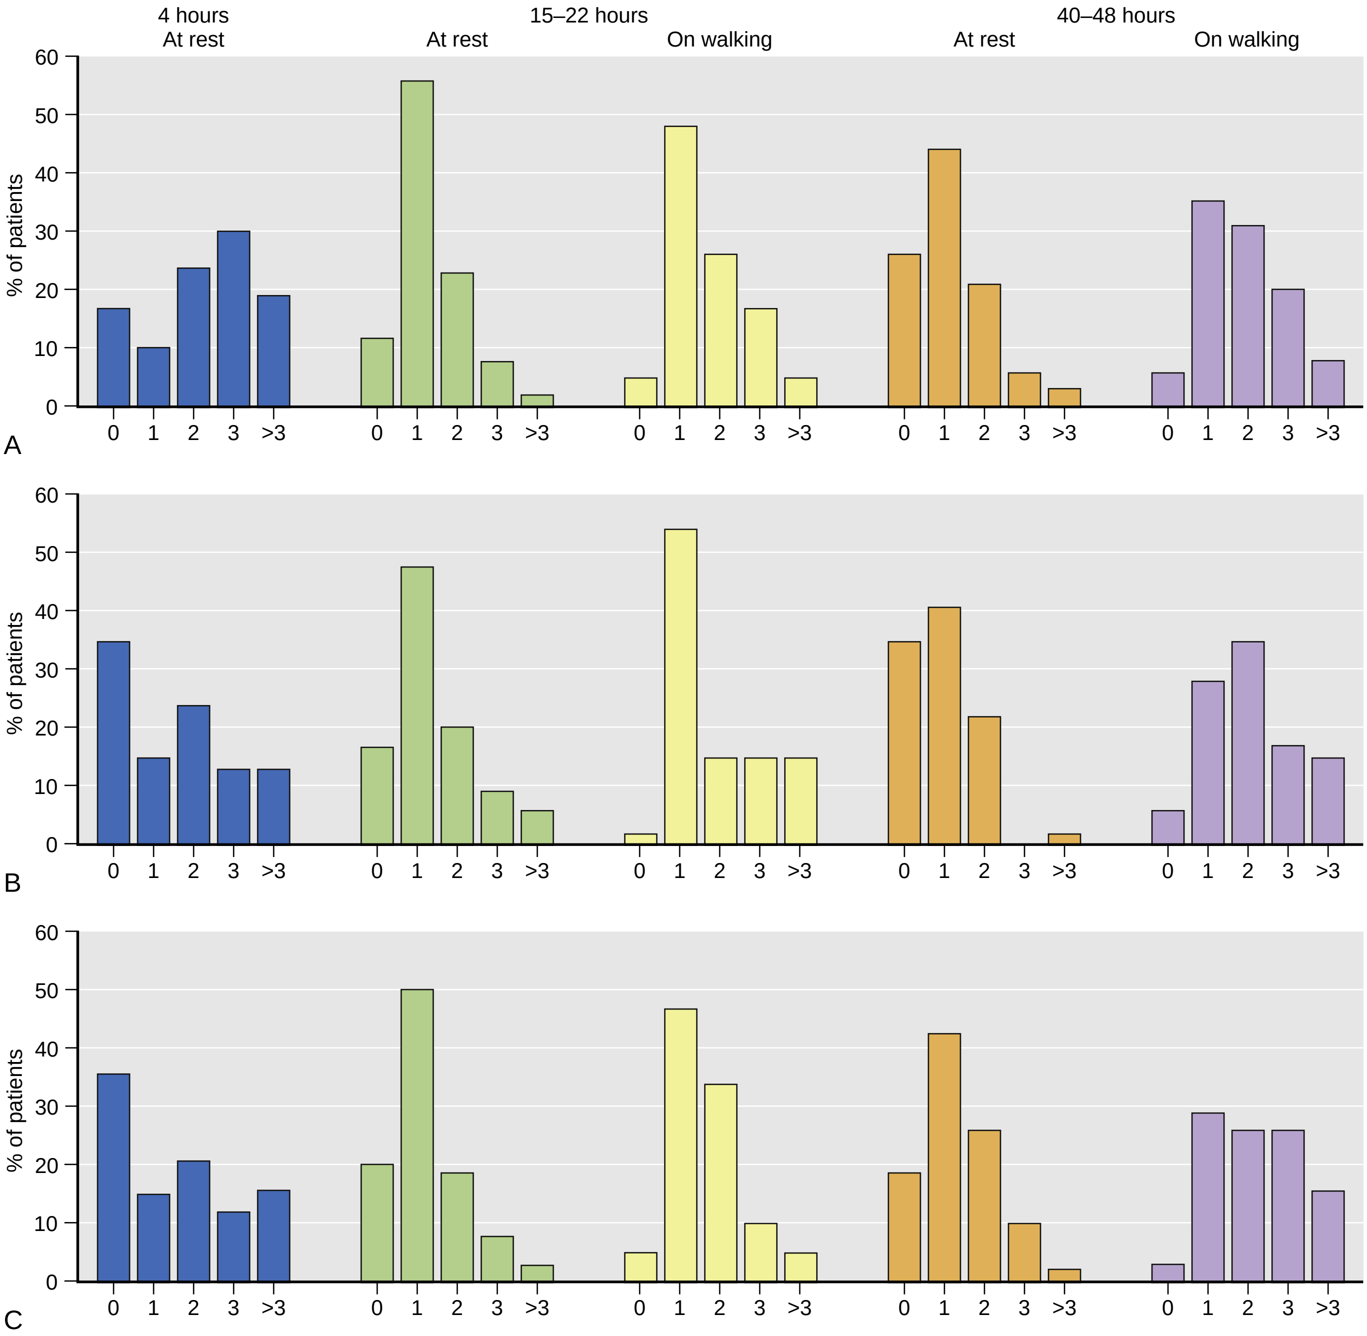

Fig. 72.2 **Numerical pain scores at various time points after hip resurfacing arthroplasty (A; *n* = 185), total hip replacement (B; *n* = 54), and total knee replacement (C; *n* = 86) in patients receiving local infiltration anesthesia.** (Data from Kerr DR, Kohan L. Local infiltration analgesia: a technique for the control of acute postoperative pain following knee and hip surgery: a case study of 325 patients. *Acta Orthop.* 2008;79[2]:174–183.)

is usually adequate and interventions are not required to maintain a patent airway. With deep sedation, the patient can respond purposefully only to repeated or painful stimuli and may require a degree of airway or ventilatory support. Far from being discrete, these sedative levels lie on a continuum (Fig. 72.3), which becomes general anesthesia when the patient loses consciousness and is unarousable even with painful stimuli.[324] Careful monitoring is essential, and the standard of care for patients receiving sedation should be the same as for patients undergoing general or regional anesthesia and includes all of the usual aspects of anesthesia care.[325] Unfortunately, a widely held belief among physicians and patients is that sedation is a safer form of care,[326] but an ASA closed claims database analysis revealed that the risks for death or permanent brain damage are similar to those of general anesthesia.[327] Predictably, the greatest risk for harm comes from respiratory depression by opioids and sedative-hypnotic drugs, and many cases could have been prevented by better monitoring and improved vigilance.[328]

The US term monitored anesthesia care (MAC) is sometimes erroneously used to describe sedation administered by an anesthesiologist. However, the ASA has a specific

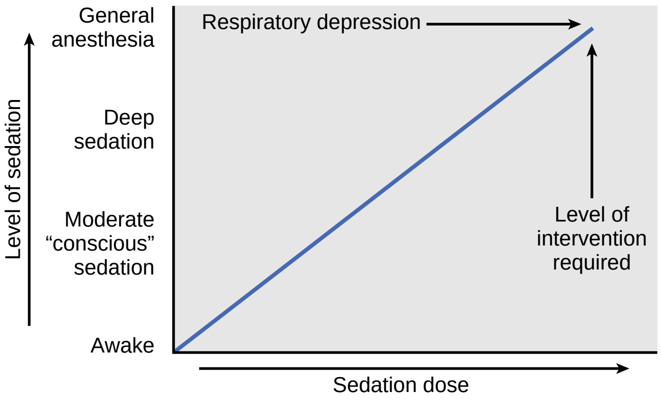

Fig. 72.3 The continuum of sedation and general anesthesia. (Reproduced from Ahuja M, Armstrong I. Sedation. In: Smith I, McWhinnie D, Jackson I, eds. *Day Case Surgery*. London: Oxford University Press; 2012:109–132. With permission.)

definition of MAC, which is a billing term used to describe an anesthesia service that includes all perianesthesia aspects of care.[325] MAC may include varying levels of sedation, including conversion to general anesthesia, when necessary. However, "if the patient loses consciousness and the ability to respond purposefully, the anesthesia care is a general anesthetic, irrespective of whether airway instrumentation is required."[325]

Choice of Sedatives

The specific requirements for supplemental sedative and analgesic drugs depend on the procedure undertaken, the skill of the operator in using local anesthesia, and the experiences and expectations of the individual patient. The use of pharmacologic agents can be reduced by compassionate patient management at every stage, preoperative explanation, and the use of distractions, such as deep breathing, conversation, and listening to music.[326] Adjuvant drugs should be chosen to deliver those specific aspects that are required,[329] such as reduction of anxiety, sedation to relieve boredom or aid immobility, and analgesia for pain that is not amenable to further infiltration of local anesthetic.

Midazolam

Midazolam produces anxiolysis and dose-related hypnosis and is a popular component of sedation. It also produces marked antegrade amnesia. At times this may be beneficial, but it is not always welcomed by patients.[330] Midazolam is preferred to other benzodiazepines because it is water-soluble, does not cause venoirritation or pain on injection, is rapid-acting, and has a relatively short-elimination half-life of about 2 to 4 hours. As sole anesthetic, a single dose of 0.05 to 0.1 mg/kg allows reasonably predictable recovery after brief procedures, but individual responses are highly variable.[331] Recovery is also considerably slower if repeat or prolonged administration is required.

Propofol

Propofol is an excellent sedative-hypnotic because its pharmacokinetic properties result in a rapid recovery from the effects of a single bolus dose and a continuous infusion. Propofol is a relatively pure hypnotic, providing no analgesia and only moderate amnesia. Infusion rates of 25 to 75 μg/kg/min are typically used,[332] but the short duration of action facilitates titration to effect.

Because of the excellent conditions that can be achieved and the superiority of recovery compared with that of midazolam,[333] demand for propofol sedation is growing rapidly in areas such as endoscopy in which anesthesiologists have not traditionally been involved. Propofol can rapidly cause apnea, before loss of consciousness, even in sedative doses, and unintended transition to general anesthesia is a constant risk. The safety of nonanesthesiologist administration of propofol is therefore controversial. In the United Kingdom, the Royal College of Anaesthetists and the British Society of Gastroenterology jointly state that propofol sedation for complex upper GI endoscopic procedures should be administered only by an "appropriately trained anaesthetist."[334] In the United States, the FDA package insert states that propofol may be given "only by persons trained in the administration of general anesthesia," which the ASA supports.[335] However, the American Society for Gastrointestinal Endoscopy considers propofol use safe by anyone "proficient in the management of upper and lower airway complications, including manual techniques for reestablishing airway patency" and holding at least basic life support certification.[336]

Advocates of endoscopist-administered propofol claim a very low rate of airway complications (0.1%) and a mortality (4 in 646,080) less than that associated with endoscopist-administered midazolam-opioid sedation.[337] Their data also reveal a wide range for the frequency with which rescue airway support was required, suggesting considerable variation, either in technique or willingness to intervene to protect the airway.[337] When anesthesiologists administered propofol for patients undergoing endoscopic retrograde cholangiopancreatography (ERCP), deeper levels of sedation or general anesthesia were often intended and sedation-related adverse events were far more common (21%), especially in patients of higher ASA physical status classification, but were managed without adverse consequence or delay, and high levels of patient and operator satisfaction were achieved.[338] A more recent study of anesthesiologist-administered propofol sedation has revealed a very similar (23%) incidence of significant unplanned events.[339]

Potential New Sedatives

Fospropofol was a water-soluble phosphate ester prodrug of propofol, with a slower onset of action and longer duration. Although approved in the United States for sedation in adults in 2009, restriction of its use to anesthesiologists[340] and a lack of any clear advantage over propofol prevented its commercial success.

Remimazolam is a new ester-based benzodiazepine, designed to be rapidly broken down by ubiquitous tissue esterases into an inactive metabolite. Preliminary findings suggest a faster onset and shorter duration than midazolam after a single dose,[341] although not all procedures could be completed without "rescue" sedation. Remimazolam may have a role as a sedative for brief (<10 minute) procedures, but its behavior after repeated dosing and its consequent role as a sedative have yet to be evaluated.[341]

Analgesic Adjuvants

Opioids are useful for procedures in which pain cannot reliably be blocked with local anesthesia alone.[323] Compared to alfentanil in women undergoing breast biopsy, remifentanil resulted in lower pain scores during deep dissection and reduced the need for supplemental local anesthesia.[342] Remifentanil was a useful adjuvant to propofol sedation during transvaginal tape insertion[343] and in achieving optimal conditions for awake craniotomy,[344] surgery that is increasingly being performed as a day and short-stay procedure.[26] Remifentanil produced lower pain scores than fentanyl in patients receiving propofol sedation during hysteroscopy, but it did not improve recovery or patient satisfaction.[345] For hysteroscopic surgery, paracervical block supplemented by a remifentanil infusion permitted earlier mobilization and discharge compared to TIVA, and the sedation technique was also preferred by a higher proportion of patients. Remifentanil is usually delivered by infusion, but intermittent bolus doses may be more effective for some procedures.[346] Hyperalgesia after remifentanil administration remains a concern.

Both clonidine and dexmedetomidine have potentially useful analgesic, anxiolytic, and sedative properties. The slow onset and offset of clonidine and frequent reports of cardiovascular instability mean that neither drug has established a routine place in sedation,[148,347] although dexmedetomidine may be a useful analgesic adjuvant in awake craniotomy.[348] Ketamine improved analgesia when used to supplement propofol sedation, but an increase in PONV, psychomimetic side effects, and delayed discharge were observed at higher doses.[349]

Delivery of Sedation

Because of the varying needs to provide hypnosis, anxiolysis, analgesia, and amnesia, use of drug combinations is common during anesthesiologist-administered sedation. Preceding a propofol infusion with a 2 mg dose of midazolam improved anxiety, sedation, and amnesia for early intraoperative events with no detrimental effect on postoperative sedation, amnesia, or recovery times.[350] However, using drug combinations increases the risk for interactions, leading to adverse effects. At sedative doses, propofol and remifentanil each have only a modest effect on heart rate and arterial blood pressure, but their effect on respiration is strikingly synergistic, with the potential for severe respiratory depression.[351] Respiratory depression is also enhanced by the interaction of midazolam and remifentanil.[352] Antagonists of benzodiazepines and opioids may be useful in cases of unintended overdose, but should not be routinely relied on to reverse deep sedation because of their short duration of action, which may permit resedation before[353] or after discharge.[354] It is also possible to achieve high rates of patient satisfaction without procedural recall when using intermittent bolus doses of propofol alone for endoscopic procedures.[355]

As with TIVA, the stability and control of sedation regimens can be improved by using TCI systems.[356] Target concentrations of 0.5 to 2 μg/mL for propofol and 0.5 to 1 ng/mL for remifentanil are typical,[323,347] but should be titrated to individual effect. Effective sedation is usually judged by clinical endpoints or scores. Bispectral index (BIS) changes with increasing sedation, but is too variable[357] to be useful routinely and was not effective as an endpoint for midazolam sedation.[358] BIS monitoring did not improve the quality of sedation or reduce the propofol dose or rates of hypoxemic, bradycardic, or hypotensive complications during ERCP.[359] However, BIS-guided TCI propofol may be useful in the management of patients with intellectual disability,[360] in whom clinical signs may be less reliable. Allowing patients to adjust their own sedation level by patient-controlled sedation resulted in less propofol being used compared with a continuous infusion and was significantly more popular with patients.[361] However, this approach necessarily requires comparatively light levels of sedation and appears to be an undesirable option for a significant proportion of patients.[362]

Inhaled sedation by a low dose of sevoflurane is an alternative technique that provides good control of sedation and rapid recovery.[363,364] However, it can be complicated by a frequent incidence of perioperative excitement and an increased risk for transition to general anesthesia.[365]

Monitoring Depth of Anesthesia

Many devices are now available to monitor the hypnotic component of anesthesia as a supplement to our traditional reliance on autonomic signs. Most monitor electroencephalogram signals, recorded either spontaneously or evoked in response to a stimulus, which are then processed into a dimensionless number, usually ranging from 0 to 100. Precisely which variables are recorded and how they are processed can be proprietary information,[366] and the specific values corresponding to adequate anesthesia also vary among monitors.[367]

BIS was the first licensed monitor and is the most extensively studied, yet whether it can actually prevent awareness with recall remains controversial.[367] In ambulatory anesthesia, in which awareness is uncommon,[368] more interest has been shown on whether BIS and similar devices can reduce excessive anesthetic delivery, thereby improving the speed and quality of recovery and reducing costs. Two meta-analyses have shown that titrating anesthesia to achieve BIS values of 40 to 60 results in trivial (2-4 minutes) reductions in awakening times, shortens recovery room stay by just 4 to 8 minutes, and fails to facilitate earlier home discharge.[369,370] BIS titration also produced a very modest reduction in PONV (32% vs. 38%).[369] Despite reductions in anesthetic drug usage, the cost savings were substantially less than the disposable costs associated with BIS.[369] Monitoring with auditory evoked potentials achieved similar small reductions in drug usage and awakening times, comparable to those seen with BIS.[371,372] Discharge times were unchanged in one study[371] but were shortened by both BIS and auditory evoked potential monitoring in another study in a very similar population.[372] Spectral entropy monitoring also achieved only small reductions in drug use and recovery times, although the quality of evidence was rather poor.[373]

Although a lack of clear clinical or financial benefit exists from depth of anesthesia-guided drug titration, genuine concerns have been raised about using these monitors for purposes other than those for which they were designed. Although anesthesia is usually adequate at values below 60, BIS lacks a high level of discrimination and some patients may form memories at values as low as 40.[374] Thus, titrating anesthesia, even to BIS values of 40 to 50, to reduce costs and recovery times, may unintentionally increase the risk for awareness.[366]

Recovery from Ambulatory Anesthesia

Recovery is traditionally divided into three stages. Early, phase 1 recovery occurs in a postanesthesia care unit (PACU) and entails further awakening and management of pain and nausea, with monitoring of hemodynamic stability. Intermediate recovery continues in the phase 2 (step-down) recovery or in a separate ward area and ends when the patient achieves the criteria for home discharge (see later discussion). The phase 1 and phase 2 aspects of recovery may occur in separate locations or within the same room.

EARLY RECOVERY

The recovery room or PACU should be centrally placed to all operating rooms and requires the same standard of staffing and equipment as are provided for inpatients.[375] The PACU may be shared with inpatients in some facilities, but recovery times can be shortened dramatically if there is a separated phase 1 PACU dedicated to ambulatory patients.[11] In the United States, the ratio of nurses to patients is usually lower than in the inpatient PACU, for ambulatory typically 1:3, reflecting the lower acuity of postprocedural needs.[6] Patient care should be adequately transferred to the PACU nursing staff, relaying preoperative and intraoperative problems and postoperative instructions. The nature and frequency of monitoring in the PACU is determined by the nature of surgery and the state of recovery. Because ambulatory anesthetics are typically short-acting, supplemental oxygen (O_2) administration may be unnecessary in the PACU,[376] provided the patient's saturation level of O_2 in hemoglobin (SpO_2) remains above 92% on air.

In the United Kingdom, patients may be discharged from phase 1 to phase 2 of recovery when they are awake and oriented, normothermic, able to maintain their own airway and ventilation, and demonstrate cardiovascular stability. Wounds should be reasonably dry, and pain and PONV should be minimal and adequately treated. This assessment is usually made on clinical judgment.[375] In the United States, transfer from phase 1 to phase 2 is commonly based on predefined, physician-determined criteria. Typical ambulatory criteria include being awake with stable vital signs, minimal pain, minimal nausea, and the ability to sit with minimal dizziness.[377] If more standardized data are desired, a scoring system can be used. The most commonly used system is the modified Aldrete score,[378] which assigns points on the basis of activity, ventilation, blood pressure, consciousness, and oxygenation (Table 72.4). Length of PACU stay is one of the key endpoints, along with awakening, orientation, and extubation times used to evaluate early recovery in ambulatory anesthesia research.

TABLE 72.4 The Modified Aldrete Recovery Score

		Score
Activity:	Able to move 4 extremities voluntarily or on command	2
	Able to move 2 extremities voluntarily or on command	1
	Unable to move extremities voluntarily or on command	0
Respiration:	Able to breathe deeply and cough freely	2
	Dyspnea or limited breathing	1
	Apneic	0
Circulation:	BP ± 20% of preanesthetic level	2
	BP ± 20%-49% of preanesthetic level	1
	BP ± 50% of preanesthetic level	0
Consciousness:	Fully awake	2
	Arousable on calling	1
	Not responding	0
Oxygenation:	Able to maintain saturation >92% on room air	2
	Needs oxygen to maintain saturation >90%	1
	Saturation <90% even with oxygen	0

The total possible score is 10; patients scoring ≥ 9 are fit for discharge from phase 1 recovery. *BP*, Blood pressure.

SECOND-STAGE RECOVERY

Second-stage recovery prepares patients for leaving the ambulatory surgery unit and taking over their own care. Patients should sit upright on trolleys or reclining chairs as an aid to mobilization. After low-dose spinal anesthesia, mobilization is usually possible within an hour of the return of full motor function, or about 2.5 to 3 hours after the start of spinal anesthesia.[172,379]

FAST-TRACK RECOVERY

With the increased use of short-acting drugs and techniques, many patients will have already met the discharge criteria before, or by the time, they reach the PACU.[380] If this is the case, admission to the PACU will only generate unnecessary delay while further observations are performed. Instead, these patients may bypass phase 1 recovery and go directly to the phase 2 unit; this is known as fast-track recovery.

The modified Aldrete score can also be used to assess fast-track eligibility.[381] Because this score does not assess pain or PONV, which are traditionally treated in the PACU, White and Song[382] added two additional categories to derive their fast-track recovery score. Although using this score reduced the proportion of patients who met the fast-track criteria on PACU arrival, it also significantly reduced the number of patients who required parenteral analgesia or antiemetics in the step-down area.[382] Others have suggested a series of clinical criteria[383] that must all be achieved for patients to undergo fast-track recovery (Box 72.1). The criteria for transfer from phase 1 to phase 2 and the criteria for direct entry to phase 2 should be the same.

Fast-track recovery is the norm for patients who have had local anesthesia, but it is also appropriate for most patients receiving sedation[383,384] and low-dose spinal anesthesia in the United Kingdom.[172] Patients receiving general anesthesia also may be able to undergo fast-track recovery, which is appealing because improved recovery provides the patient with a higher-quality experience, enabling them to return toward normal in a more pleasant, comfortable, and facilitative environment. It also frees up the more intensive resources of phase 1 recovery for those patients who need them.

Accomplishing fast-track recovery is complex. In one facility, fast-track recovery was only achieved in just over 60% of those who met the PACU bypass criteria.[385] The use

BOX 72.1 Criteria* for Direct Admission to the Second-Stage Recovery Unit, Bypassing the Post-Anesthesia Care Unit

Patient should be awake, alert, oriented, responsive (or returns to baseline state)
Pain should be minimal (unlikely to require treatment with parenteral medications)
No active bleeding should occur (unlikely to require professional treatment)
Vital signs should be stable (unlikely to require pharmacologic intervention)
Nausea should be minimal
No vomiting should occur
If nondepolarizing neuromuscular blocking agent has been used, patient should now be able to perform a 5-second head lift, or train-of-four monitoring should indicate no fade
Oxygen saturation should be 94% or higher on room air (3 min or longer) or oxygen saturation should return to baseline on room air

*During the follow-up period, the patient should be evaluated in the operating room, immediately before discharge, using the above criteria regarding recovery from anesthesia. To bypass the post-anesthesia care unit, a patient must meet all of these criteria and, in the judgment of the anesthesiologist, be capable of transfer to the second-stage recovery unit.

of depth of anesthesia monitoring has been claimed to facilitate fast-track recovery,[386] whereas others have not found it advantageous.[387] Accomplishing fast-track recovery requires not only anesthesia recovery readiness, but also the support of a facility-based process, including nursing and surgeon participation and environment support.

The economic case for fast-track recovery should be considered separately.[388] In some cases, fast-track recovery has shortened overall recovery stay, comparable to,[389] or even longer than,[383] the time that would have been spent in the PACU. However, nursing workload was not reduced,[389] while others have found no difference in overall recovery time.[385] Nurses in the step-down unit are not always readily available to receive patients and often report patients arriving cold or without all the fast-track criteria actually being met.[390] Although fast-track recovery appears financially beneficial, actual savings will be made only if the PACU is not needed at all or if staffing levels can be reduced, which is not supported by the evidence to date.[388] Nursing workload and costs may simply be shifted from one area to another, with no overall savings.[389] Fast-track recovery may still help to improve patient flow and may work best in small units that use staff flexibly between different areas.[388] But the most productive approach may be to enable the fastest possible path for all patients through their recovery to discharge home.

Postoperative Pain

The management of postoperative pain should begin well before the patient undergoes surgery. Patients need to have appropriate expectations about what they are likely to experience during their recovery.[391] At preoperative assessment, patients should be provided with information about the likely extent and duration of pain after surgery. They should also be advised about simple measures to reduce pain, including advice to rest in a comfortable position, raising swollen limbs, use of heat or cold packs, and the benefits of distraction. Prevention is the mainstay of pain management, yet studies have shown that pain management after ambulatory surgery is often inadequate.[392-394] Common causes are a lack of adherence to analgesic guidelines and a failure to provide multimodal analgesia.[394] Too often there is over-reliance on opioid analgesia, resulting in predictable adverse effects,[395] that are second only to inadequate pain relief in causing unnecessary hospital admission.[392]

MULTIMODAL ANALGESIA

Multimodal analgesia relies on the additive or synergistic combination of drugs acting at various points on the pain pathway.[396] Typical combinations include local anesthetic wound infiltration or regional techniques and routine NSAIDs, with small doses of opioids added as needed. Topical therapies may also be of some benefit, with both lidocaine and glyceryl trinitrate patches found to provide effective topical analgesia after a variety of ambulatory procedures.[397] Multimodal regimens have been shown to be effective after several ambulatory surgical procedures.[398,399] An opioid-sparing effect exists for several drug combinations,[400] but most evidence is limited to an opioid plus one other drug, with little evaluation of true multimodal analgesia or attempts to identify optimal combinations.[394] Analgesic efficacy appears to differ with the nature of surgery,[401] suggesting that multimodal analgesic regimens should be specifically tailored.[402] Nevertheless, reducing the opioid dose does decrease the incidence of PONV to a corresponding degree and may also reduce other opioid adverse effects, such as sedation, sleep disturbances, urinary retention, and respiratory depression.[395] As yet, no evidence indicates that multimodal analgesia improves long-term patient outcome[403] because of the small number of subjects studied and the infrequent incidence of adverse outcomes after ambulatory surgery.

RESCUE ANALGESIA

Despite prophylactic measures, some patients will experience pain on awakening after surgery. Milder cases may be amenable to treatment with additional oral analgesia, but more severe pain will usually require parenteral opioids. Long-acting parenteral opioids are rarely indicated. Fentanyl is commonly used for this purpose, and small boluses (20-25 μg) rapidly achieve analgesia. Compared to morphine, fentanyl results in more rapid control of pain and reduces the occurrence of PONV.[404] Rescue fentanyl also produced fewer adverse effects than oxycodone.[405] Administration of additional oral analgesia as soon as the pain is controlled will usually prevent a recurrence at a later stage of recovery. During the recovery period, pain should be assessed on a regular basis and treated according to protocols (Fig. 72.4).

PAIN MANAGEMENT AT HOME

In the United States, patients are often given prescriptions for postoperative analgesics, including weak opioids,

preferably before surgery so the medications will be at home when the patient needs them. In the United Kingdom, patients may be given standardized take-home analgesic packs that can be dispensed from the ambulatory surgery unit, avoiding pharmacy delays. Typical take-home analgesia includes NSAIDs and acetaminophen combined with a weak opioid. Combinations of codeine-acetaminophen[406] and hydromorphone-acetaminophen[407] are effective after many ambulatory surgical procedures, although a proportion of patients are unable to metabolize codeine to its active form, rendering it ineffective.[408] Although a single preoperative dose of pregabalin produced modest improvements in pain after ambulatory surgery, continuing its use into the postoperative period added no further benefit.[167]

Managing Opioid Complications

Although multimodal techniques aim to minimize opioid use, strong opioids can be necessary as a rescue option after more invasive surgery. Analgesics such as morphine and oxycodone provide more intense and prolonged effects, but are associated with more intense and prolonged typical opioid side effects. Novel delivery techniques, such as iontophoretic[409] or nasal[410] fentanyl, or sublingual sufentanil,[411] may improve patient convenience but do nothing to reduce adverse effects. In addition to multimodal analgesia, attempts to limit these adverse effects have included the development of drugs such as tramadol, which combine opioid and nonopioid mechanisms of action. Tramadol is effective after ambulatory surgery,[412,413] but it is still associated with a frequent incidence of unwanted effects, including sedation, dizziness, and particularly PONV.[414] Tapentadol is licensed in both the United States and the United Kingdom. It has a dual action similar to that of tramadol, with comparable efficacy to oxycodone but fewer GI adverse effects, such as nausea, vomiting, and constipation.[415] Unlike tramadol, it does not require metabolic activation or suffer from isomer-dependent pharmacodynamics.[163]

Combining oral oxycodone with naloxone (Targinact) antagonizes the GI effects, in particular preventing opioid-induced constipation, but has little effect on analgesia because first-pass metabolism prevents much naloxone from reaching the central nervous system.[163] Alvimopan is another peripherally acting µ-opioid (MOP) receptor antagonist intended to reduce opioid-induced constipation. However, peripheral MOP receptors also may partially mediate opioid-associated PONV, delayed gastric emptying, and urinary retention,[163] offering the hope that opioid analgesia without serious adverse effects may yet be a possibility.

Local Anesthetic Administration at Home

Sending patients home with perineural, incisional, and intraarticular catheters is a new and evolving area of postoperative pain management.[416] Patient-controlled regional anesthesia (PCRA) with an elastomeric balloon pump has provided effective analgesia and reduced pain intensity during mobilization when ropivacaine is delivered into a perioperatively placed wound catheter after subacromial decompression.[417] Although patients were kept in hospital for study observations and assessments, based on pain scores, the authors concluded that all patients in the active group could have been discharged within 2 hours of surgery. Another small pilot study showed excellent analgesia with continuous interscalene block, continued at home, allowing same-day discharge after a variety of shoulder operations, including open rotator cuff repair, subacromial decompression, and joint replacement.[418]

Recently, several institutions have described cases of chondrolysis that appear to be related to the use of postoperative intraarticular local anesthetic pain pumps.[419] In a series of 375 patients from one individual orthopedic surgeon, chondrolysis was observed only in cases in which either bupivacaine or lidocaine had been infused into the joint during the postoperative period.[420] Most local anesthetics, including bupivacaine, lidocaine, and ropivacaine, are chondrotoxic to human articular cartilage in vitro, and the risk may be increased with longer exposure to higher concentrations of local anesthetic, such as with a pain pump, compared to that associated with a single injection.[421] Consequently, the use of local anesthetic infusions after shoulder surgery has declined or stopped in many institutions.

A variety of infusion pump designs are available for local anesthesia infusions or PCRA after discharge. Technical problems have been found with electronic pumps,[422] which seem to be unreliable for home use.[418] Patient satisfaction[422] has been reported with disposable elastomeric pumps, which are more reliable, although not all types function equally well and in vivo performance does not necessarily match results obtained in vitro.[423]

Postoperative Nausea and Vomiting

PONV occurs in as many as 30% of a general surgical inpatient population given no antiemetics.[424] Some patients undergoing day surgery have a much smaller risk for symptoms, cited as less than 5%[56,425] for very minor surgery, with reduced requirement for intraoperative and postoperative opioids. However, in the same studies, other ambulatory surgery patients had a predischarge incidence of PONV as high as 41%. When the potential occurrence of emetic sequelae after discharge is included in the estimation of overall risk, some authors cite an overall incidence of more than 40%, even after receiving an antiemetic.[426]

RISK ASSESSMENT AND STRATEGIES

Some have recommended that the management of PONV for ambulatory patients should involve universal multimodal pharmacologic prophylaxis to minimize the symptoms that might delay timely discharge or subsequent recurrence in the home environment.[427] However, current recommendations[428] advocate a more focused approach toward the use of preventive pharmacotherapy, having first minimized baseline risk resulting from the use of generic emetogenic stimuli, such as adequate hydration, the use of local-regional techniques, or if a general anesthetic is needed, reducing exposure to volatile anesthetics, N_2O, and opioid-based analgesia. Avoiding neostigmine was previously advocated, but may not be beneficial.[428] Individual patient factors should then be identified to stratify relative risk. The scoring system originally derived from a cohort of ear, nose, and throat patients by Apfel and colleagues in 1998[429] is popular because of its relative simplicity; yet debate continues regarding discriminating power[427] and its applicability to ambulatory surgery patients, because the predicted risk for PONV (Table 72.5) seems to be overestimated in this population, presumably as a result of the original scoring system having been developed for inpatients in Europe. This seems to be confirmed in a subsequent paper by the same author,[426] where PACU-only rates of nausea were 19.9%, vomiting 3.9%, and nausea and/or vomiting 20.7% across an ambulatory patient cohort with characteristics that would seem to predict greater risk from the original algorithm. In the same study, postdischarge rates of PONV until the second postoperative day were however higher: 36.6% nausea, 11.9% vomiting, 13.3% severe nausea, and 5.0% severe vomiting. From these data, the authors developed a predictive scoring algorithm for postdischarge nausea and vomiting (PDNV) (Table 72.6). Other scoring algorithms exist for prediction of risk for PONV in the ambulatory environment, but their relative complexity mandates the use of a calculator or computer.[425] A reevaluation of risk factors for PONV[430] reiterated the importance of those characteristics included in the original Apfel score,[424] but this algorithm included younger age and duration but not type of surgery. A simple policy whereby two antiemetic interventions were administered to all male patients and three to all females[431] resulted in better compliance and greater effectiveness than several previously published strategies,[432] although at the risk of exposing more patients to the potential harm of unnecessary antiemetics.

PACU, Post-anesthesia care unit; *PONV*, postdischarge nausea and vomiting.
Data from Apfel CC, Philip BK, Cakmakkaya OS, et al. Who is at risk for postdischarge nausea and vomiting after ambulatory surgery? *Anesthesiology*. 2012;117(3):475–486.

Antiemetic treatment should therefore be tailored to assessment of likely risk for symptoms with the use of either unimodal or multimodal prophylaxis as indicated. The IMPACT study[200] demonstrated that ondansetron 4 mg, droperidol 1.25 mg, and dexamethasone 4 mg were equally effective in reducing the risk for PONV by an order of 25% and that using these two drugs together would be approximately additive (multimodal antiemetic prescription). Specifically, the prophylactic use of one of these drugs decreases the estimated risk for PONV from 60% to 44%; use of two drugs would further decrease the incidence from 44% to 33% and three drugs to 24%. The use of TIVA with propofol with the concomitant avoidance of N_2O had similar equivalence to the use of one antiemetic.[200] However, the antiemetic effectiveness of TIVA is time-limited and patients receiving TIVA appear to have a higher risk of late PONV, starting 2 to 6 hours after surgery.[200A] Simple measures, such as the routine administration of approximately 1 to 2 L of intravenous crystalloid fluids, reduce the incidence and severity of PONV, decrease dizziness and drowsiness,[433] and reduce postoperative pain in high-risk groups.[434] Allowing patients to drink clear liquids for as long as possible before surgery can also reduce PONV.[124]

ANTIEMETIC AGENTS

First-Generation Drugs

Metoclopramide is a dopaminergic (D_2) and serotonergic (5-HT_3, peripheral 5-HT_4 at higher doses) antagonist with gastric prokinetic properties that was first described in 1964. A meta-analysis of a standard clinical dose of 10 mg showed little evidence of pharmacologic benefit for PONV,[435] but after a number of studies by Fujii were withdrawn, reanalysis suggests that there may be some benefit.[436] However, current guidelines still do not list metoclopramide for first-line treatment.[428] Higher doses, such as 20 to 25 mg, are more effective[437] but are associated with more akathisia.

Droperidol is a butyrophenone with an antiemetic effect resulting from dopaminergic receptor (D_2) antagonism that received a black box warning for the FDA-approved dose of 2.5 mg[438] or greater because of potential QT interval prolongation. This and other side effects of droperidol, such as sedation and akathisia, were significant but at higher doses than are commonly used for PONV prophylaxis,[438] which are typically 1.25 mg or less. A recent meta-analysis[439] has confirmed the antiemetic action of low-dose droperidol. Droperidol use is less in the United States since the black box warning was added but primarily for medicolegal reasons rather than because of concerns with efficacy or side effects. It is also little used in the ambulatory environment in the United Kingdom due to perceptions of adverse extrapyramidal effects, particularly akathisia, even at 0.5-mg doses.[440,441] An Australian study evaluating the incidence of akathisia in 228 women undergoing ambulatory gynecologic laparoscopy reported a rate of 29% with administration of 10 μg/kg.[442]

Antagonists of the histamine H_1 receptor have a particular efficacy in the management of nausea and vomiting precipitated by vestibular pathways, with a documented benefit in the management of travel sickness and surgical procedures for strabismus or involving the middle ear. Dimenhydrinate (a combination of diphenhydramine and 8-chlorotheophylline that was added to reduce drowsiness) has an antiemetic effectiveness deemed similar to that of both droperidol and 5-HT_3 antagonists,[443] but potential adverse reactions from these antihistamines include marked sedation, dry mouth, urinary retention, and blurred vision as a result of associated muscarinic receptor antagonism. Meclizine, an H_1-receptor antagonist and anti–motion sickness medication, is minimally sedating, long-acting, and effective for treatment of PONV and for prevention of PDNV.[444] In the United States, it is inexpensive and available without prescription, making it an attractive postdischarge choice.

A transdermal scopolamine delivery system is also available. This patch was designed to deliver a total dose of 1 mg of scopolamine at a sustained, constant rate over a period of 3 days.[445] Numerous studies have shown transdermal scopolamine to be effective in reducing the incidence and severity of PONV and PDNV, with efficacy comparable to that of ondansetron or droperidol. It has a prolonged duration but the onset is delayed, becoming effective within 2 to 4 hours of applying the patch.[446] The slow onset can be overcome by applying the patch the night before surgery. Used in this way, the incidence of nausea and vomiting was reduced from 62.5% and 37.5% to 20.8% and 8.3%, respectively, compared to placebo after gynecologic laparoscopy.[447] In the United States, clinicians apply the patch preoperatively, knowing that onset of PDNV efficacy will be in the early recovery period for shorter surgery.[445] Adverse effects, particularly dry mouth but also somnolence, dizziness, and blurred vision, are relatively common but generally described as mild.[445,447]

Serotonin 5-HT3 Receptor Antagonists

The 5-HT_3 antagonists have played a substantial role in the management of PONV since their introduction in the 1980s, because of their relatively benign adverse reaction profile compared with those of the then available drugs. Their prophylactic use is more effective when given just before the end of surgery.[448] They are effective drugs for emetic rescue therapy, with ondansetron seeming to have a more preferential effect on vomiting (number needed to treat [NNT] = 4) rather than nausea (NNT = 7).[449] Although relatively well tolerated, their side-effect profile includes an increased risk for headache (number needed to harm [NNH] = 36) and elevated liver enzymes (NNH = 31).[449] All serotonin subtype 3 antagonists have also been associated with QT interval prolongation. More recently released serotonin 5-HT_3 receptor antagonists, such as dolasetron, granisetron, and palonosetron,[450] seem to exhibit similar characteristics with equal reduction of PONV rates in high-risk patients when used for prophylaxis, though the longer half-life of these drugs (8, 10, and 40 hours, respectively) may afford better protection against symptoms after discharge. In particular, palonosetron, by nature of its unique binding properties leading to internalization of the 5-HT_3 receptor[451] and a long half-life, may have a role in the management of postdischarge symptoms.[452] A large cost remains a significant barrier to use of the newer, nongeneric serotonin antagonists.

Steroids

Dexamethasone is an effective antiemetic at intravenous doses of 4 to 5 mg (depending on local formulation).[453]

This steroid may act centrally to either modulate the release of endorphins or inhibit prostaglandin synthesis. Given its delayed onset of action, dexamethasone should be administered as early as possible *after* induction of anesthesia.[454] Prophylactic dexamethasone is also effective in reducing postoperative pain and improving the quality of recovery,[169,170] although at somewhat higher doses (typically 8 mg) than those required for an antiemetic effect. The long-term side effect profile of this dose of dexamethasone has not yet been evaluated.

Neurokinin-1 Antagonists

The role of tachykinins in the emetic pathway was first elucidated by immunohistologic studies identifying substance P in the dorsal vagal complex of the ferret, an area of the brain deemed essential in the vomiting reflex.[455] Subsequent research identified the potential value of specific antagonists to the neurokinin-1 receptor, at which substance P and neurokinins A and B interact both centrally and peripherally in the gut to suppress vomiting. Aprepitant was the first commercially released drug of this class. A preoperative oral dose of 40 mg has efficacy similar to that of ondansetron for the reduction of nausea, with a potentially superior effect in the suppression of vomiting for 48 hours after administration.[456] An intravenous prodrug formulation, fosaprepitant, was more effective than ondansetron in preventing vomiting, but not nausea, and with no effect on complete response rates for PONV in small numbers of patients undergoing gynecological[457] or lower limb[458] surgery. A multicenter study evaluating the use of oral rolapitant,[459] a competitive NK-1 antagonist with an exceptionally long half-life of 180 hours, suggested similar effectiveness in comparison with placebo and ondansetron (administered at induction) with early control of symptoms, but use of rolapitant similarly seemed to confer prolonged protection from postoperative emetic symptoms. Rolapitant does not seem to have been further evaluated in PONV and cost remains a barrier for this class of drugs as well.

MANAGING PERSISTENT NAUSEA AND VOMITING

The presence of continuing symptoms after antiemetic rescue therapy requires further clinical review. Consideration should be given to alternative causes for these symptoms, particularly hydration status, covert hypovolemia, or early infection. Review of vital signs (temperature, pulse, and arterial blood pressure), allied with clinical examination to exclude an association with concomitant worsening of abdominal pain, potential septic foci, or urinary retention, is important to exclude more sinister causes, before consideration is given to symptomatic relief.

Administering 20 mL/kg of an isotonic electrolyte solution reduces the risk for nausea and dizziness after ambulatory surgery and volume repletion should be considered to attenuate continuing symptoms.[433,460] Ephedrine 0.5 mg/kg intramuscularly is effective for prophylaxis and treatment, with efficacy comparable to that of droperidol and sedation scores lower than placebo.[461] No value exists in prescribing a previously used antiemetic drug within 6 hours of previous administration,[428] but other second-line drugs may be considered should first-line management fail. These options include small-dose promethazine (6.25 mg); small-dose intravenous naloxone; propofol 20 mg; phenothiazines, including prochlorperazine, perphenazine, or a neurokinin antagonist. For patients who have not received prophylaxis, the 5-HT$_3$ antagonists are the preferred treatment of PONV and the class of drugs with best proven efficacy for treatment rather than prophylaxis.[428]

Special Areas

OFFICE-BASED PRACTICE

Office-based anesthesia is a form of ambulatory anesthesia that is rapidly expanding in North America and some parts of Europe. Arguably, the first ambulatory surgery center in the United States (the Downtown Anesthesia Clinic in Sioux City, Iowa) was an office-based practice.[2] Simple, minimally invasive surgical procedures have been performed in physicians' offices for many years, using either local anesthesia or sedation. There is now a growing involvement of anesthesiologists, especially as the complexity of office-based surgery increases.

Advantages of office-based surgery include improved convenience for the patient, but the primary driver has been more control over scheduling and the work environment for the surgeon. The potential exists for significant profit going directly to the surgeon, but in addition, the lower overhead costs in this setting result in significantly lower overall costs for the procedure. For example, the total cost of a laparoscopic inguinal hernia repair was three and a half times greater when performed in a hospital setting compared with an office facility.[462] The costs of open hernia repair[462] and various rhinology procedures[463] were approximately 2.5 times less when performed in the office. In the United States, office-based surgery covers a wide range of procedures.

However, legitimate concerns have been raised about the safety of office-based surgery. One comparative study showed a more than 10-fold increase in adverse incidents and deaths for procedures performed in a physician's office compared with an ambulatory surgical center.[464] These disasters are often the result of unqualified or untrained individuals administering sedation in unsuitable or unaccredited facilities.[464,465] Deep sedation appears to be a considerable risk factor. From the ASA closed claims database, 40% of the deaths resulting from MAC occurred during facial and eye surgery, which are commonly performed in the office setting.[327] Hypoxia and hypoventilation resulting from oversedation was the most common cause of death, with poor vigilance, inadequate monitoring, and delayed resuscitation contributing to the deaths, half of which were judged to be preventable.[327] The common perception that sedation is safer than general anesthesia is not supported by these data.

In the United States, the regulation of office facilities is the responsibility of individual states, with nearly 30 states having some degree of oversight as of 2014.[466] Regulation does appear to improve safety, because no deaths were reported in a series of more than 23,000 cases from a fully accredited office staffed by board-certified anesthesiologists and surgeons.[467] In addition, safety appears to be improving

BOX 72.2 A Summary of Office-Based Surgery Practice Guidelines Collated from US Regulatory Bodies

Employment of appropriately trained and credentialed anesthesia personnel
Availability of properly maintained anesthesia equipment appropriate to the anesthesia care being provided
As complete documentation of the care provided as that required at other surgical sites
Use of standard monitoring equipment according to the American Society of Anesthesiologists policies and guidelines
Provision of a postanesthesia care unit or recovery area that is staffed by appropriately trained nursing personnel and provision of specific discharge instructions
Availability of emergency equipment (e.g., airway equipment, cardiac resuscitation)
Establishment of a written plan for emergency transport of patients to a site that provides more comprehensive care should an untoward event or complication occur that requires more extensive monitoring or overnight admission of the patient
Maintenance and documentation of a quality assurance program
Establishment of a continuing education program for physicians and other facility personnel
Safety standards that cannot be jeopardized for patient convenience or cost savings

in parallel with greater regulation.[466] Guidance on office-based anesthesia is available from the ASA and SAMBA,[468] and comprehensive recommendations from other organizations and experts have been published. Typical recommendations for safe office-based anesthesia are summarized in Box 72.2. In essence, the office setting must adhere to the same standards of care required in a hospital-based or freestanding ambulatory surgery facility. Strong safety processes must be in place, because the isolated office-based environment means that outside help is not immediately available.

The selection of patients for office-based anesthesia should adhere to robust guidelines for safe anesthetic care. Because perioperative complications are harder to manage in an isolated environment, selection criteria may need to be more restrictive than those currently advocated for ambulatory surgery in the hospital setting.[46] The selection process must include a matrix of procedure invasiveness, patient complexity, and the capabilities and comfort levels of the facility and its personnel.[468] Preoperative preparation should be guided by the same clinical acumen and common sense that drives the decision-making process at freestanding surgery centers, with any coexisting diseases under good control. Anesthetic techniques suitable for office-based surgical procedures are similar to those used for hospital-based and freestanding ambulatory surgery procedures. MAC remains common, although clearly a great challenge exists in "the judicious and skillful use of MAC anesthesia to achieve adequate sedation and analgesia for increasingly invasive procedures."[469] Increasingly a move toward light general anesthesia is occurring—that is, using an LMA or facemask for airway management.[470,471] Propofol, sevoflurane, and desflurane are all suitable within the office setting, although an anesthesia machine is required to deliver volatile anesthetics. Standard equipment can be installed in frequently used offices, and portable equipment has been developed for less frequent use.[465] Fast-track recovery is the ideal with patients who are awake, alert, and able to transfer themselves from operating room table to a reclining chair, thus facilitating room turnover in approximately 10 minutes and home discharge within an hour of awakening.[465] It is important to minimize PDNV.[472] Recommendations have been made for other outcome measures that should routinely be audited after office-based anesthesia.[468,473] The American Medical Association and American College of Surgeons issued a set of Office-Based Surgery Core Principles to promote safety and quality of healthcare services for office procedures requiring sedation and anesthesia.[474]

In the United Kingdom, a similar practice of office-based anesthesia for dental procedures was in place for several decades. A series of anesthetic deaths in dental offices led to several reviews, culminating in recommendations that all anesthetics be administered by accredited anesthesiologists with specific training and experience in dental anesthesia, as well as recommendations regarding resuscitation equipment and the availability of drugs needed for emergency use.[475] Partly because of the high costs of equipment and maintenance, the net result was the movement of all anesthesia out of the dental office and back into the hospital environment.[476] Subsequently, office-based anesthesia has never developed in the United Kingdom. Minor surgery under local anesthesia is performed in some specially equipped primary care surgery centers, whereas the majority of procedures that are performed in offices in the United States are managed in hospital-affiliated day surgery units, procedure rooms, or surgical outpatient clinics in the United Kingdom.

ANESTHESIA IN REMOTE LOCATIONS

Many surgical conditions that formerly needed treatment in a hospital outpatient operating room are now being managed by interventional procedures done by nonsurgeon physicians in radiology, cardiology, and endoscopy (see also Chapter 73). In many cases, deep sedation or anesthesia is still required, meaning the anesthesiologist has to move into unfamiliar and often hazardous environments. The problems associated with these diverse locations are considered in detail in Chapter 73, but because many of the procedures are performed on an ambulatory basis or require anesthetic management according to all of the usual short-stay principles, a brief description is required here. The basic sedative and anesthetic techniques already described are suitable for most cases, but the conduct of anesthesia is likely to have to be modified according to the specific environment.

Administration of anesthesia or sedation at remote locations is associated with significant risk.[477] Some of these risks are specific to particular areas (Table 72.7) but commonly include an unfamiliar environment; small, cramped, or dark rooms; restricted patient access; inadequate or poorly trained support; restrictions on patient monitoring; and inadequate resources. An analysis of ASA closed claims arising from anesthesia care in remote locations revealed that adverse events had a higher probability of death than those arising in the operating room[478] and were primarily caused

TABLE 72.7 Some of the Hazards Associated With Anesthesia in Remote Environments

Area	Examples of specific hazards
Magnetic resonance imaging (MRI) scanner	Noise. Strong magnetic fields; no ferromagnetic equipment within scanner. Peculiarities of MRI-compatible equipment. Remote monitoring may introduce delays (e.g., capnography). Risk of induced currents causing burns in coiled cables. Compliance and dead space within extra-long breathing circuits
X-ray and interventional radiology	Radiation exposure; mobility limited by lead gowns. Often low light levels. Restricted access and unexpected movement of x-ray equipment. Patients may have significant comorbidities. Allergic reactions to contrast media. Limited patient access in CT scanner
Endoscopy suite	Dark environment, limited access. Patients may have significant comorbidities. Risk of hemodynamic disturbance with bowel preparation or vagal stimulation. Shared airway in upper endoscopy. ERCP performed in prone position with added hazards of radiology
General issues	Unfamiliar environment. Old or unfamiliar equipment. Emergency drugs and equipment may be rarely used or checked. Lack of dedicated or trained assistance. Scavenging may be difficult or absent

CT, Computed tomography; *ERCP*, endoscopic retrograde cholangiopancreatography.

by an adverse respiratory event (44%). MAC was the most common anesthetic technique, and respiratory depression secondary to oversedation accounted for over a third of the claims. Care that was substandard and preventable by better monitoring was implicated in the majority of claims associated with death.[478] In the United States, the CMS mandates that the chiefs of anesthesia services monitor and evaluate sedation practices throughout the hospital, and accrediting organizations, such as TJC and DNV, audit for compliance.

Home Readiness and Beyond

PATIENT INFORMATION

Before discharge, patients should receive postoperative instructions concerning aftercare, their transition to normal activities, and any requirements for follow-up. These instructions should be in writing[479] because retention of information is impaired during early recovery from anesthesia,[480] and ideally they should be repeated to the patient's escort. Besides general advice, discharge information should include the early warning signs for the main complications of the specific procedure the patient has undergone[479] and the action to take should these occur.

CRITERIA FOR DISCHARGE

BOX 72.3 **Criteria for Facility Discharge Used at the Brigham and Women's Hospital, United States**

Alert and oriented to time and place
Stable vital signs
Pain controlled by oral analgesia
Nausea or emesis mild, if present
No unexpected bleeding from operative site
Able to walk without dizziness
Patient has been given discharge instructions and prescriptions
Patient accepts readiness for discharge
Adult present to accompany patient home

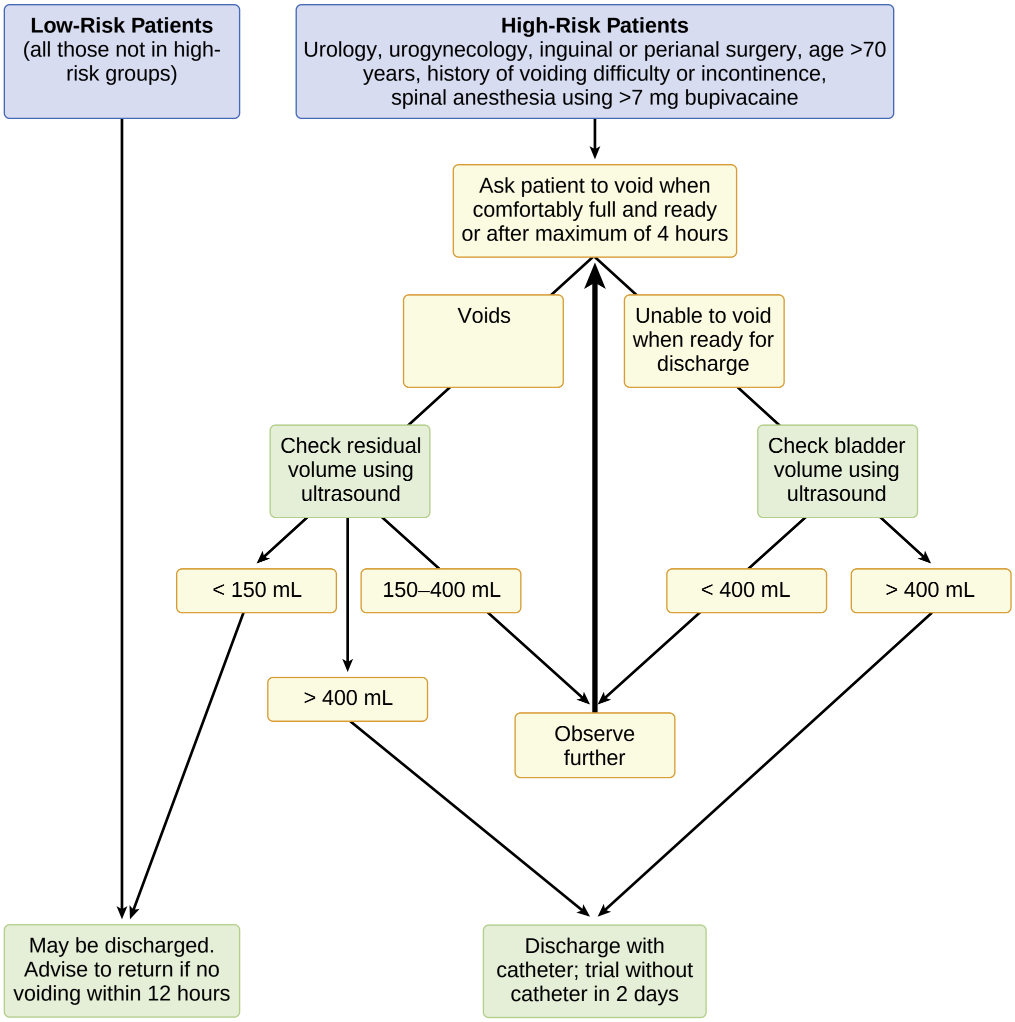
Courtesy of B K Phillip.

Discharge of the patient after ambulatory surgery and anesthesia is a physician responsibility in the United States,[10] fulfilled by physician-written discharge criteria (Box 72.3). Typically, patients should be oriented and comfortable with cardiovascular stability (including when standing) and problem-free wounds. Alternatively, discharge criteria may be incorporated into a scoring system, such as the Post-Anesthetic Discharge Scoring System.[481] Voiding urine is no longer considered an essential prerequisite for discharge in those at low risk for urinary retention, even after spinal anesthesia.[482] For patients at higher risk, the bladder volume should be assessed by ultrasound scanning[483] and the patient managed accordingly (Fig. 72.5). Actual discharge is frequently nurse-managed,[479,484] provided patients have been managed according to an appropriate protocol and have met all the necessary discharge criteria.

No rationale exists for a minimum observation period after ambulatory surgery in most cases, although patients clearly must be observed for a sufficient period to ensure cardiovascular stability. One possible exception is tonsillectomy, in which a minimum observation period of 6 to 8 hours has been advocated to detect most primary hemorrhages.[31] However, even this has been challenged, with a 4-hour observation period[485,486] or less[487] regarded as safe.

AFTERCARE AND FOLLOW-UP

Appropriate aftercare is one of the main safety features of ambulatory surgery. Acute complications may be related to anesthesia or surgery, and patients should receive careful predischarge education about what may occur for both. All patients should be provided with a 24-hour telephone number for emergency contact. This is often the ambulatory surgery unit during the daytime, but it may be necessary to provide another number or better still to automatically transfer calls when the unit closes at night.[479] In the United States, patients are also routinely given their surgeon's office and answering service number to contact directly for surgical issues. Although the United Kingdom healthcare system includes primary care doctors, they have limited experience in potentially life-threatening early postoperative complications and should not be called first. If the patient's call to the facility or physician does raise concerns, it is important that the patient be brought back for early surgical review; going to the emergency department also can introduce unnecessary delay. Because the ambulatory patient is self-caring and likely to mobilize early, symptoms of surgical complications are noticed and reported sooner



Low-Risk Patients
(all those not in high-risk groups)
High-Risk Patients
Urology, urogynecology, inguinal or perianal surgery, age >70 years, history of voiding difficulty or incontinence, spinal anesthesia using >7 mg bupivacaine
Ask patient to void when comfortably full and ready or after maximum of 4 hours
Voids
Unable to void when ready for discharge
Check residual volume using ultrasound
Check bladder volume using ultrasound
< 150 mL
150–400 mL
< 400 mL
> 400 mL
> 400 mL
Observe further
May be discharged. Advise to return if no voiding within 12 hours
Discharge with catheter; trial without catheter in 2 days

Fig. 72.5 Flowchart illustrating the management of patients who fail to void urine after ambulatory surgery. (Reproduced from British Association of Day Surgery. Spinal anaesthesia for day surgery patients. London [available from http://www.bads.co.uk]; 2010. With permission.)

than if the patient were recovering in the hospital environment, allowing earlier detection and increased safety. Daily assessment of various recovery parameters at home using a smartphone-based app was popular with patients and also appeared to improve quality of recovery, probably by providing additional reassurance.[488] The system could also be used to request contact from a nurse and was found to be more cost-effective than other forms of postdischarge contact,[489] although others found a simple telephone call, which would be cheaper still, was similarly effective.[490]

Follow-Up and Outcome Measures

The ASA has developed a set of outcome indicators specifically for ambulatory and office-based surgery and anesthesia.[491] These include outcome events of interest for days 1, 14, and 30 and ongoing continuous quality indicators. The IAAS[492] has developed a series of indicators (Table 72.8) useful in the evaluation of the overall success of organizational performance, and these mirror the advice from other national specialist societies.[46,493] Lemos and Barros[494] further defined the value of outcome reporting in a range of domains subdivided into clinical, organizational, social, and economic factors that allows the reporting of both individual and institutional performance (Table 72.9). Return-mail questionnaires can be used for patient follow-up after ambulatory surgery to help identify common sequelae that ambulatory patients should realistically expect to experience.[391] No matter how data are collected, it is important that information from quality indicators is fed back in an effective way to individual clinicians and clinical units to support continuous improvement.[495]

Adverse Effects After Ambulatory Surgery

Minor adverse events are common after ambulatory surgery and anesthesia (86%).[391] Drowsiness is the most common effect persisting after discharge (62%), and aches and sore throat are common in intubated patients (47% and 49%, respectively). Headache (25%) and dizziness (20%) also occur, but nausea and vomiting after discharge are less common (17% and 7%, respectively). Patients may take 2 to 3 days before they are able to resume their usual activities.[391] Information about these known side effects should be incorporated into the preoperative patient education and, in the United States, may be incorporated in a separate consent for anesthesia.

TABLE 72.8 Outcome Indicators for Ambulatory Surgery Suggested by the International Association for Ambulatory Surgery

Indicator	Reason
Failure to attend the ambulatory surgery center/unit	Acute medical condition Decision of the patient Organizational reasons Other reason (explain...)
Cancellation of the booked procedure after arrival at the ambulatory surgery center/unit	Pre-existing medical condition Acute medical condition Organizational reasons Other reason (explain...)
Unplanned return to the operating room on the same day	
Unplanned overnight admission	Surgical reasons Anesthetic or medical reasons Social or administrative reasons
Unplanned return of the patient to an ambulatory surgery unit or hospital	<24 h >24 h and < 28 days
Unplanned readmission of the patient to an ambulatory surgery unit or hospital	<24 h >24 h and < 28 days

TABLE 72.9 Outcome Measures in Ambulatory Surgery

Category	Specific Outcome Measures
Clinical	Perioperative cardiovascular and respiratory adverse events Minor postoperative morbidity: pain nausea and vomiting other: sore throat, headache, drowsiness Unplanned return to the operating room on the same day of surgery Unplanned overnight admission Unplanned return or admission to the day surgery unit or hospital: <24 h >24 h and < 28 days
Organizational	Proportion of elective surgery performed as day case Accessibility to ambulatory surgery programs: number of different procedures included Cancellation of booked procedures failure to arrive at the ambulatory surgery unit (ASU) Cancellation after arrival at the ASU
Social	Patient satisfaction Functional health status and quality of life
Economic	Efficiency rate of operating room utilization

ASU, Ambulatory surgery unit.

Reproduced from Lemos P, Barros F. Outcome measures. In: Smith I, McWhinnie D, Jackson I, eds. *Day Case Surgery*. London: Oxford University Press; 2012:335–344. With permission.

Acute cardiovascular events (hypertension and hypotension, dysrhythmias, cardiac ischemia, and arrest) occur with an overall frequency of 2.9%, with greater risk in patients with preexisting cardiovascular morbidity; respiratory events (hypoxemia, laryngospasm, bronchospasm, aspiration, pulmonary edema, and pneumothorax) occurred in 0.1% of the study population, with increased risk in smokers, asthmatics, and the obese.[57] Unanticipated overnight admission has a worldwide reported incidence of between 1% and 6%. Caution is required in the use of this indicator as a standard to achieve, however, unless the reasons for the admission are documented. Although the indicator may provide evidence of inadequate preoperative assessment and patient optimization, differences in surgical case mix and complexity may explain any variation across institutions. Ultraconservative selection criteria could result in an extremely low overnight admission rate and inappropriately give the impression of a highly performing unit rather than one that was excessively cautious with patient selection. Cross comparison of this indicator with rates of ambulatory care as a proportion of all elective surgery, either by specialty or specific operation, could assist with interpretation.

Patient Satisfaction With Ambulatory Surgery

Patient satisfaction is a difficult metric to define, depending somewhat on the patient's expectation of care. Nevertheless, patient satisfaction is generally very high after ambulatory surgery. The patient experience was improved when facility staff was thought to be friendly and the surgeons discussed findings before discharge,[496] and these factors were perceived by postoperative ambulatory surgery patients as being more important than management of postoperative pain, starting the intravenous line smoothly, and avoidance of delays. Others have found that provision of accurate information about the expected perioperative process is important; other factors that lead to higher satisfaction are effective postoperative analgesia, minimal emetic sequelae, staff courtesy and privacy in the unit, short waiting times before surgery, no perception of being rushed, postoperative telephone contact, and naturally, good surgical outcome.[492]

Non-Operating Room Anesthesia

MABEL CHUNG and RAFAEL VAZQUEZ

KEY POINTS

- The non-operating room arena represents an expansion of the traditional environment for anesthesia practice with significant implications for patients and providers. As technology advances and patient acuity increases, non-operating room anesthesia (NORA) cases have become more demanding in terms of both patient management and required resources and support services.
- Financial and operational constraints create additional challenges. Significant differences in practice result from the fact that NORA cases occur in places remote from the operating room (OR) and are performed frequently by medical proceduralists who are less familiar with the scope and clinical issues related to the practice of anesthesiology. In addition, anesthesiologists may be less familiar with the demands of providing an anesthetic in an environment outside of the OR and, in some cases, in which the proposed procedure and needed equipment restrict mobility and access to patients or where radiation exposure or other risks pose other challenges.
- This chapter serves as a general guide to the key principles of anesthetic management associated with procedures performed outside of the OR, and highlights some of the adaptations, both cultural and practical, that must be addressed in order to provide safe and optimal care that meets the need of the providers and patients.

Overview: Defining Non-Operating Room Anesthesia—What It Is and How We Got Here

Non-operating room anesthesia (NORA) refers to all procedures performed in locations other than the operating room (OR) and includes diverse environments and procedures, often associated with challenges not regularly confronted for procedures performed in the OR. Historically, cases managed outside of the OR were minor, infrequent, and involved relatively stable patients with limited comorbidities. They seldom required involvement of an anesthesia provider; more commonly sedation, if needed, was provided by a nurse supervised by the proceduralist. Over the past 2 to 3 decades, NORA cases have expanded considerably, now involving care provided by every medical specialty and, for many hospitals, accounting for increasing volume and revenue equivalent to that of the OR. Most important for the anesthesiologists is that the NORA cases are now often as demanding as the most advanced surgical OR procedures. They constitute a major expansion of our practice perimeter and require the same, if not more, planning and attention to operational efficiency as is required for cases performed in the OR.

In the United States, the number of NORA cases has continued to climb over the past decade. The percentage of cases increased from 28% to 36% from 2010 to 2014 alone.[1] This continued escalation of NORA procedures now requiring the care of an anesthesia provider is based on rapid technologic developments and innovations that have expanded the array of possible procedures ranging from simple same-day procedures to complex cardiac procedures that necessitate postprocedure monitoring and care in the intensive care unit. Anesthesiology support is also required because patients with underlying medical conditions and increasing age are now being offered procedures that were previously unavailable to them. As a result, an increasing number of patients undergoing NORA procedures are older and more likely to be classified as having American Society of Anesthesiologists (ASA) class III-V physical status as compared with patients undergoing procedures in the OR.[1] In fact, many NORA cases are performed on patients deemed "high risk for surgery," including patients who in the past would not have been considered candidates for any medical intervention. Although some of these "minimally invasive" procedures are considered to be lower risk for the patient, the anesthetic issues are often very complex with significant potential for physiologic changes that require intensive management.

The increase in procedures performed outside of the OR has been accompanied by increasing oversight related to the safety of anesthesia in remote locations. An analysis of the ASA Closed Claims database found that remote location claims demonstrated a higher proportion of claims for death compared with OR claims (54% vs. 29%) and involved older and sicker patients. Fifty percent of remote location claims involved monitored anesthesia care—a reflection of the importance of close monitoring and management of patients by a skilled anesthesia provider who is able to transition the management to include initiation of general anesthesia or other interventions to address complex clinical issues.

Predictably, respiratory events and inadequate oxygenation and ventilation were more common in these remote location claims than in OR claims.[2] These findings suggest that patients are at a higher risk of adverse events when undergoing anesthesia for procedures in remote locations. These data underscore the need for conscientious preparation and greater vigilance when caring for patients in these environments. The goal of anesthesia providers must be to mitigate systemic factors that contribute to the excess hazard in these environments.

The purpose of this chapter is twofold: first, to highlight the inherent, common, as well as the unique characteristics of NORA cases that impose unusual challenges for anesthesiologists providing care outside of the OR; and second, to describe the goals, methodologies, and pitfalls of interventions in these environments that might be unfamiliar to some anesthesiologists. This chapter does not reiterate basic principles of anesthesiology practice described elsewhere in the text, nor does it describe the technical details of novel procedures. Instead, it serves as a general guide to the NORA environment and procedures performed outside of the OR and delineates some of the critical issues faced by anesthesiologists. The intention is to promote awareness that encourages preemptive planning, and equips anesthesia providers with a vocabulary with which to establish effective dialogue to cultivate a collaborative practice with colleagues and to maximize the safety of patients.

NOVEL CHARACTERISTICS OF NORA CASES

NORA cases are characterized by three distinctive features: location, operator, and relative novelty. First, the procedure does not take place in a standard operating suite and is typically remote to the main OR section. Second, the operator performing the procedure is generally a medical interventionalist rather than a surgeon. Finally, the procedures and technologies used are constantly evolving. Innovative applications of these procedures and technologies pose a challenge for a number of reasons as well. With advances in technology and expertise of the operators performing procedures outside of the OR, the procedures can be performed on patients with complex comorbidities and often on patients who are not candidates for a traditional surgical procedure or for whom surgery is no longer the only therapeutic option. For example, carotid artery stenosis can be treated in the OR, the catheterization laboratory, or the interventional radiology (IR) suite. The ultimate choice of venue may be a function of acuity of presentation but often depends on the referral—who the patient sees first, and who is available. As important, for many patients undergoing a NORA procedure, the scheduling is urgent, emergent, or unknown to the anesthesia provider until immediately before the procedure is to be performed, preventing an adequate periprocedural evaluation. These ever-expanding clinical services requiring anesthesia services outside of the OR provide an opportunity for anesthesiologists to reevaluate and reaffirm the importance of a preoperative assessment, as well as periprocedural and postprocedural needs, for this diverse group of patients. As a result, the perimeter of our landscape has expanded beyond the familiar domain of the OR and requires collaboration with a broad array of medical practitioners including interventional cardiologists, interventional radiologists, gastroenterologists, radiation oncologists, and electrophysiologists. Given the physical, medical, political, and economic challenges that may arise and that are often unanticipated, the goal must be to adapt to the new environments. We must also strive to evolve our anesthesia practice to meet the demands of a changing patient population.

UNIQUE OBSTACLES: FROM PHYSICAL ENVIRONMENT TO THE MEDICINE–ANESTHESIOLOGY CULTURE GAP

When anesthesiologists are faced with the need to provide services for non-surgeons in non-OR locations, issues such as scheduling inconsistencies, ad hoc requests, and resource limitations can be difficult to resolve, particularly if the usual scheduling process is not available. In addition, the increasing incidence of medically complex cases with patients needing urgent intervention, but lacking periprocedural evaluation, can create challenges. The two most common challenges are poor communication between providers exacerbated by the medicine–anesthesiology culture gap and, for many of the NORA procedures, inadequate physical space to accommodate the needs of a patient requiring anesthesia services.

Procedural suites are often remotely located. This increases the time lag between a request for assistance and the arrival of help, both with technological and medical problems. In addition, the lack of nearby supplies may exacerbate the timely resolution of common electrical and mechanical malfunctions or complicate the resolution of a medical emergency. This situation demands that care be taken before the start of the procedure to ensure that equipment is supplied and working and that backup options (emergency supplies, difficult airway equipment) are functioning and readily available.

In addition, non-OR procedure suites are frequently organized from the perspective of the proceduralist, and unfortunately, the needs of anesthesiologists are often overlooked. For example, procedure suites that use fluoroscopy for guidance are often configured so that the C-arm limits access to the patient's head and obstructs direct communication between the anesthesiologist and the proceduralist. Inadequate access to the patient may be exacerbated if the area around the head of the patient is crowded due to constraints of the room and equipment. Lack of visibility of procedural screens may also make it difficult to follow the progress of the intervention without compromising the attention to the patient. Perhaps most important, hemodynamic monitors may be difficult to visualize by the anesthesiologist or, for some procedures, may not function properly because of interference with mapping systems or other electronic interfaces. Lead protective screens may not be available, and when they are available and positioned to protect the anesthesiologist from radiation, pumps and intravenous lines may become inaccessible. Gas scavenging may be unavailable, and oxygen and suction outlets may be suboptimally placed. For these and other reasons, anesthesiologists should be mindful of how best to orient both the patient and providers spatially within a procedure room, particularly if the setup of the room is unfamiliar. Distraction of focus away from patient care due to an unfamiliar environment can be potentially disastrous in the face of a novel or complex procedure.

The ASA has formulated a statement regarding NORA locations that articulates minimum standards for all procedures performed in these areas,[3] but these standards are quite fundamental. Recognition of the constraints of the environment and anticipatory planning allow for the safe administration of anesthesia within this environment. The challenge is communicating the importance of these issues to the proceduralist and others involved in the care of the patient as well as hospital leadership to ensure that the needs of all parties are met. With newer procedures requiring anesthesia services in nontraditional environments, there may be a need to implement significant environmental changes to optimize the ability of anesthesiologists to deliver safe care.

Communication with the medical proceduralist is key to providing an optimal anesthetic; taking time to discuss the procedure and the patient allows for thoughtful consideration of anesthetic options in the context of both the principles of the procedure and the physiology of the patient. However, mismatches in culture can dominate interactions between medical practitioners and anesthesiologists and undermine communication. These conversations can be challenging since, unlike surgeons, medical providers may be unfamiliar with the skill sets of anesthesiologists and the needs for patient care or unaware of the intricacies associated with administering an anesthetic. For example, while surgeons are accustomed to sharing their procedures with other medical practitioners, proceduralists may be habituated to working alone and ordering sedation to be administered by a nurse. Medical interventionalists may also lack experience with relatively rare but serious complications that might arise during the procedure, such as loss of airway. In addition, proceduralists are frequently consultants who are enlisted by primary care providers to perform procedures, but who may not have received all relevant information that may be needed for a patient requiring anesthesia services. Even when all information is provided, specialization predisposes the proceduralists to concentrate on their point of expertise, so many of the concerns of the anesthesiologists are not taken into account.

Similar issues regarding the needs of the patient and the proceduralist may not be taken into account by the anesthesiologist who is unfamiliar with the procedure. In many cases, the anesthesiologist may have only a basic understanding about what is happening during the course of a noninvasive procedure and may not have asked enough questions about the plans, especially when they are new to a particular venue, the procedure is not observable, and fluoroscopy screens are out of the field of view or uninterpretable. Anesthesiologists may be unaware of pitfalls and likely complications of the procedure even though in the OR, they normally would not administer an anesthetic without understanding the idiosyncrasies of the surgery. These issues are important in planning for the anesthesia and procedure but are equally important during the procedure. Extra initiative is often required by the anesthesiologist since the proceduralist may not communicate the course of the procedure during the case. Other aspects of the procedure, such as how coughing on extubation might predispose patients who have had groin sheaths to serious hematomas, may not have been emphasized by the procedural team or likewise appreciated by anesthesiologists. Bridging the communication gap requires effort, but it is absolutely critical to optimizing outcomes.

When interventionalists undertake novel procedures using new technologies, the situation can become even more challenging. The course of the procedure may be unknown, the timing and sequence of events may be ill-defined, and the focus of the procedure may change midstream. At times, the proceduralist may be unsure of what is happening. In these situations, extensive preplanning, a commitment to communication, and the explication of goals for all involved in the care of the patient is crucial to the success of the procedure and, more importantly, the safety of the patient.

As medical procedures, particularly those performed outside of the OR environment, become even more technically demanding and patient clinical conditions more complex, the best possible patient management strategies will arise from collaboration and teamwork between medical proceduralists and anesthesiologists. This requires mutual respect, excellent communication, common vocabulary, shared experience, and overlapping competencies. In pursuit of this goal, we can build on the outstanding record of improved patient safety and outcomes that characterizes the history of anesthesiology.

FINANCIAL AND OPERATIONAL CONSTRAINTS

The impact of performing procedures in new environments has significant financial and operational implications that must be addressed. In the desire and enthusiasm to advance clinical care and extend care to settings outside of the operating room, medical, financial, and operational implications often become blurred. As a result, it is important to understand the difference between what does and what should drive the direction of new program development related to NORA procedures and for all parties to address the specific operational needs while taking into account the financial implications of transitioning care to these alternative settings.

EFFECTS OF PAYMENT SYSTEMS

A variety of payment methodologies are used to compensate providers and facilities for clinical services. While government payment methods remain important, private insurance has become the financial underpinning of the healthcare system in the United States—often allowing hospitals and providers to advance new technologies and innovative care that would otherwise be financially impossible. Private health insurance evolved as hospitals transitioned from repositories for the impoverished and dying into institutions where people actually recovered from illness. Hospitalization plans, initially developed by hospitals in the 1930s, were a way to supplement the economic resources needed for growth and expansion. At that time, hospitals often functioned as extensions of private offices and payment was, and continues to be, a fee-for-service system. As health care has become more expensive and the clinical options have expanded, both the public and private systems have had to adapt, becoming more complex and sophisticated—with the goal to minimize payment to those practices that have documented, evidence-based outcomes. These changes, and the goal to reduce costs of care, have both encouraged care outside of traditional and expensive environments, such as the OR, but also challenged providers to prove that the care remains safe and of high quality. These conflicting goals make expansion of care to non-OR locations challenging and, in some cases, undermine attempts to innovate.

Medical optimization and financial efficiency are predictably not the end products of fee-for-service payments. With increasing demand for clinical services, the need to reduce costs, hospital length of stay, and readmissions is critical. As the population ages, care is increasingly specialized and complex. The Medicare Payment Advisory Commission (MedPAC) reported that as of 2006, the average Medicare beneficiary saw five doctors per year and Medicare beneficiaries with three or more chronic conditions saw more than 10 physicians a year.[4] With advances in care, transitions of some procedures from the OR to new settings, and care provided by a "new" group of providers that previously did not perform procedures (cardiologists, neurologists, and others), more providers participate in the care of patients. The implications of these changes are numerous. For example, for patients whose care involved four or more doctors, MedPAC reported that 48% experienced medical errors, medication errors, or laboratory errors. As technology advances and the population ages, risks and benefits change and new genres of service emerge and expand. Imaging services, which have exploded across disciplines in the last decade, are now provided by radiologists, vascular surgeons, cardiologists, internists, anesthesiologists, and surgical subspecialists.[5] Traditional fee-for-service payment systems are not designed to ensure that the right treatment is performed on the right patient at the right time by the right physician in the right venue. The result is that groups of assorted medical proceduralists provide in-hospital care that is often fragmented, perpetuated by silos of specialized care despite the interdependent nature of specialty services. Coordination of care, particularly for the newer procedures requiring anesthesia services and performed outside of the OR, is needed but often not provided for a variety of reasons. Unfamiliarity with anesthesia services and requirements as well as lack of payment for coordination of care are primary reasons. This uncoordinated or fragmented care creates challenges for the patient and provider, often resulting in duplication of some service, variability of resource use, and inconsistent application of quality standards. Payment silos create misalignment of goals across specialties, creating competition rather than collaboration among disciplines and, in some cases, pitting the needs of one set of providers against another without intending to do so.

Another factor that contributes to the challenges associated with performing procedures requiring anesthesia care in NORA environments is the lag in payment for new technologies by Medicare and other payors. While delaying implementation of new procedures into the clinical environment until peer-reviewed evidence documents the value may be appropriate, particularly when new and/or proprietary, high-cost equipment is required, the lack of payment may actually contribute to higher costs of care or reduced quality.

Anesthesiologists are particularly vulnerable to inadequate or no compensation for some of the procedures performed outside of the OR. In some cases, the lack of payment is related to "historical controls"—healthier patients undergoing procedures outside of the OR with sedation provided by a nurse or proceduralist. The anesthesia service is only compensated when the patient meets criteria for "medical necessity"—and there may be inadequate documentation of the need for anesthesia care by the proceduralist. As important, for some patients there are associated services for which there may be no compensation. Routine preprocedure evaluation and postprocedure care are included in the anesthesia fee; other services often needed to optimize clinical management so the patient is able to undergo the procedure may not be compensated. Discussion of some of these issues related to payment for anesthesia services for the NORA procedures is ongoing at a national level.[6]

Some newer payment methods may help address the challenges of providing anesthesia services for procedures performed outside of the OR. Bundled payment methodologies, accountable care organizations, and the perioperative surgical home are three payment reforms intended to improve coordination and interdisciplinary collaboration. While these models of payment may effectively improve delivery of care in the most appropriate environment with improved outcomes, it remains to be seen how effective these undertakings will be in improving care. In any case, payment models remain a key determinant of behavior. It is incumbent on anesthesiologists to remain at the forefront of new developments as demand for anesthesia services in less traditional arenas broadens in an environment that diminishes control over the revenues we generate.

OPERATIONAL CONSTRAINTS

It is quite clear that despite a multitude of publications documenting significant OR inefficiency, institutional tradition, provider idiosyncrasy, and surgical convenience continue to compromise efficient OR scheduling practices and policies. Outside of the OR, these issues have even greater significance. Medical proceduralists and surgeons performing procedures in unfamiliar environments often do not understand the physical limitations that affect anesthesia care and the need for appropriate preprocedure evaluation and management, and in many cases are not aware of some of the underlying clinical conditions of the referred patient. To make matters worse, the specific procedure(s) to be performed on the patient may not be well-defined until the procedure begins while in other cases the procedure is "novel," often involving equipment and supplies unfamiliar to the proceduralist or assisting staff. All of these variables make scheduling non-OR cases extremely difficult.

With respect to scheduling and staffing non-OR cases, a number of issues must be considered, including:

1. Non-OR anesthetizing locations are often adapted to the specific procedure being undertaken and the needs of the medical proceduralist. Unlike ORs, they are noninterchangeable. They are often neither designed for nor take the needs of the anesthesia provider into account.
2. Most of the venues for these procedures are smaller and less flexible than traditional OR environments.

3. Block time may not be utilized to facilitate scheduling of NORA cases, making it difficult to utilize anesthesiology staff productively and increasing the likelihood of underutilized personnel and space.
4. Non-OR procedures may take place a long distance from the OR suite. Lack of storage space for anesthesia equipment may also impose longer turnover time and the need for additional anesthesia technical services.
5. Many non-OR procedure suites perform procedures on patients referred from outside providers or services that are booked through a central scheduling office. For most of these patients, the usual preprocedure evaluation process is not used to facilitate assessment and preparation of the patient. Periprocedural evaluations are often very cursory—if performed at all. This imposes an additional bottleneck for the anesthesiologist who may need to perform a preoperative evaluation immediately before the procedure and cancel or delay cases at the last minute.
6. Because many non-OR procedures are novel, it is difficult to estimate the length of time the procedure will take. Booking times may be unrealistic, and scheduling anesthesiology time may be difficult. Additionally, with new technology and noninvasive methods, it is very easy for the proceduralist to modify or extend the procedure after it is started.[7]

As noted, non-OR cases tend to be more variable, less predictable, and, therefore, more difficult to staff cost-effectively. Some of these difficulties are technical, but some are the result of cultural discontinuity and poor communication between anesthesiologists and proceduralists. To ensure effective management for these cases, a number of requirements should be met:

1. Prospectively establish a contract between the anesthesiology and procedural departments that encourages appropriate utilization of available time and minimization of differences between "staffed (contracted) time" and "productive time." In addition, in those environments where NORA cases cannot or are not scheduled efficiently, the department may need to define a "backstop" to compensate the anesthesia providers for "availability" time that is not associated with a specific case.
2. All non-OR cases should be scheduled and managed within the electronic database for OR cases, so that resource deployment can be planned and modified as needed.
3. Create a block schedule that takes into account all of the procedural areas and the most effective utilization of the space. The block time should account for the needs of all providers. For example, if cases in some areas tend to run late, anesthesia providers should be scheduled appropriately to reflect the actual times for the cases to be completed.
4. Implement real-time scheduling, including patient arrival times and other issues affecting utilization. Calculate earliest start times, optimal arrival times, and adjusted preoperative fasting (nothing by mouth [NPO]) guidelines for all patients. Avoid having patients sitting in preoperative holding areas for extended periods and account for postprocedure evaluation and monitoring needs wherever recovery of the patient is provided.
5. Improve specialized triage for scheduled outpatients in each procedural area to ensure that patients are appropriately evaluated and prepared for the anticipated procedure. The use of triage forms and staffing intake procedures, either locally within each environment or centrally, will minimize delays and cancellations. Ensure that the proceduralist is invested in the preprocedure process and supports the needs of the patient and anesthesia providers.
6. Oversight of periprocedural triage and postprocedure recovery areas should be provided by the anesthesia department to ensure that the appropriate preprocedure assessment has been completed and, when necessary, that additional preprocedure optimization is required. As part of the oversight process, tracking of unexpected admissions, prolonged recovery times, throughput, efficiency, length of stay, and medical outcomes should be performed and reviewed with all providers.

The scheduling of space, staff, and resources for NORA procedures should be standardized within the institution but can be performed in a number of ways. In general, the principles that apply in the OR should also be used for cases performed outside of the OR. These principles include reducing variability, scheduling to minimize variability as much as possible, and using actual institutional data to guide decision making whenever possible (i.e., real-time scheduling for blocks). In addition, the scheduling should take into account available time and actual productive time. Full schedules and adequate revenue collection should be incentivized; otherwise a subsidy of the anesthesia department is needed because the opportunity cost incurred is often significant. In situations where specific contracts for NORA cases are negotiated, the contracts should take into account full costs and not differentiate costs associated with specific procedures individually. Whenever possible, proceduralists should be involved in scheduling schemes so they are invested in the process. When the institution has specific, predefined areas in which these procedures will be performed, identifying a dedicated anesthesia team, as is done for selected OR service lines, should be considered. Identifying a dedicated team that understands the specific issues in each NORA environment and collaborates with the proceduralists, nurses, and others can greatly improve operational issues, patient and provider satisfaction, and clinical outcomes.

Transitional Priorities for Anesthesiologists Outside of the Operating Room

As more and more procedures are performed outside of the traditional OR environment, we can anticipate that there will be many new opportunities as well as obstacles to overcome. While many have already been articulated, new venues must take the same approach as has been taken so far to best meet patient and provider needs. Unusual procedural venues and practitioners who are unfamiliar with the scope and practice of anesthesiology challenge standard procedure. Adaptation requires that we confront, explain, reorient, and reinforce our traditional concepts of safe practice and standards of care. Anesthesiology as a specialty has improved OR safety enormously in the past 45 years, and as the scope of anesthesiology broadens, there is even more reason to redefine and remain steadfast in utilizing the same well-established standards of safe practice in new environments.

DEFINING INTERDISCIPLINARY SAFETY IN NON-OPERATING ROOM LOCATIONS: STANDARDIZATION, RELIABILITY, AND COMMUNICATION

The unparalleled record of OR safety established by surgeons and anesthesiologists has been dependent on implementation of standardized, routinized practice. Anesthesiologists depend on the predictable characteristics of ORs and surgical procedures to gauge the process of procedures and optimize anesthetic outcomes. While unplanned challenges arise even in the most standardized environment, a dedicated team with an understanding of the expected (and unexpected) events is best able to tailor care to meet the needs of the patient and providers. For non-OR cases, many of the standards are not predefined and the procedures often are not yet considered routine. In some cases, the technology is novel and, for some patients, preprocedure optimization is not ensured. For many procedures, anesthesia is required because of the inherent challenges and inability to predict clinical responses and needs. In each of these situations, communication at every step in the process is critical to optimizing patient care and outcomes. If communication is poor between proceduralist and anesthesiologist, the potential for error and a less-than-optimal outcome increases.

Frankel[8] and others have emphasized that environments that facilitate safety and reliability are characterized by the following:

1. Encouragement of continuous learning among all participants
2. A just and fair culture of accountability and responsibility
3. Support for teamwork
4. Data-based drive for safety and reliability
5. Effective communication and flow of information

Depending on the specific venue, routines can be defined for many NORA procedures—though for many NORA procedures, the routines may differ from those developed for specific OR procedures. Specialty-specific procedure units can accommodate each of the above with varying degrees of difficulty, depending on the medical, financial, and operational constraints and priorities in place. All of these elements are critical characteristics of a safe environment.

OTHER GENERAL CONSIDERATIONS FOR NORA CARE

A number of other processes are relevant to the practice of anesthesiology in general with some specific examples of their importance for anesthesia provided in settings outside of the OR environment. They include continuous learning, accountability, teamwork, and communication, all of which are critical to improving systems to optimize care.

Continuous Learning

The concept of continuous learning as an element of process improvement was initiated for other industries[9] but also applies to anesthesia practice and patient care. The principles associated with continuous learning have relevance to the delivery of anesthesia in environments outside of the OR suite, in large part because NORA services continue to expand and evolve. Lessons learned from current practices can be applied to new models of care delivery, while also implementing and evaluating the use of new technologies to expand anesthesia services to new patient populations and new locations. As clinical opportunities evolve and modifications are made to the delivery of anesthesia care, the use of objective data (where available) will be an essential element of the continuous learning process. Inherent to the concept of continuous learning is the need to evaluate clinical practices with input from all participants, including the patient, and to consider needs from a multidimensional perspective.

Culture of Accountability and Responsibility

As is true for all clinical environments of care, the anesthesiologist and all other providers must assume responsibility and accountability for patient safety and quality of care. An ongoing evaluation as to what is working and what is not—and an understanding of the reasons for adverse outcomes—is critical to process improvement. In some cases, individual actions may be responsible for an unanticipated event, though for many (if not most) adverse events, both individual and systems issues contribute. To successfully analyze adverse events and the contributing factors, formal root cause analyses (RCAs) with participation of all parties is most effective in defining how to avoid similar events in the future. This type of analysis can be very helpful in assessing the quality of care for patients undergoing anesthesia outside of the relatively controlled OR environment. The RCA process should be collaborative and non-punitive. If the actions of an individual need to be addressed, this process should be done using human resources or medical staff processes outside of the RCA process. We can learn how to initiate these reviews from other industries. For example, the launching and recovery of US Navy aircraft is a well-known process in which this type of outcome-focused, non-punitive review takes place.[10]

Support for Teamwork Structure

Support for a teamwork structure is a crucial foundation of successful interdisciplinary work. It requires that jobs are clearly defined, that debriefing occurs constructively and within a reasonable time frame, and that outcomes are reviewed to continually refine and improve care and reduce the likelihood of repeating errors. Fundamental to this is an attitude of mutual respect for other team members; this is often the most difficult for physicians to generate, because they are educated and trained to be self-sufficient, independent, and non-delegating. “Virtuoso teams”[11] are characterized by smart people who are opinionated, strident, and challenged by an acute need to perform. They get the job done by confronting each other and arriving at a mutually acceptable solution. Leadership is clearly important in this endeavor; conflict resolution and negotiation are significant parts of the process.

Effective Communication and Flow of Information

As is true in any clinical environment, communication among providers is critical to the delivery of care. Effective communication is particularly relevant in the care of patients outside of the OR for a number of reasons, many of which have already been outlined. Novel interventions and technologies used by proceduralists create potential for misunderstanding or unintended consequences due to unfamiliarity with the supplies, equipment, or maintenance. As is true for procedures performed in the OR, time-outs that include identification of the patient, description of underlying medical conditions that might impact care, and other relevant issues are perhaps even more important for NORA cases. In some cases, the primary proceduralist may be unaware of underlying medical conditions or comorbidities that impact anesthesia care, selection of sedatives and analgesics, and monitoring needs. The issues of concern to the anesthesia provider must be discussed with the proceduralist and those that might impact how a procedure will be performed must be discussed with the anesthesia provider, nurses, and others. Even medically correct actions on the part of the anesthesiologist or proceduralist, if not communicated to the other party, could drastically alter outcome. If, for example, the anesthesiologist supports decreasing blood pressure but fails to tell the proceduralist about the hemodynamic instability, s/he might continue under the assumption that the patient is tolerating the procedure when in fact a search for a cause for the blood pressure fall, such as evaluation for possible retroperitoneal bleed, is more appropriate. To create the same degree of safety and reliability outside of the OR as exists in the OR, compromise and adjustment of cultural and medical assumptions is required by all parties. Without good communication this cannot occur.

NON-OPERATING ROOM ANESTHESIA LOCATIONS: SOME LOGISTICAL ISSUES

Sites of Care

Potential sites for procedures performed outside of the OR continue to expand. As new sites are proposed, they must be carefully and thoroughly evaluated to ensure that care can be provided safely with appropriate monitoring and all supplies, equipment, and support are available. The needs must take into account the patient population(s) that will be served, including consideration of the complexity of the intervention and common comorbidities.

For anesthesia care provided outside of the OR, appropriate emergency supplies and procedures should be clearly identified, including posting of phone numbers or other contact information for accessing emergency help. In addition to considering the specific space needs to facilitate completion of a procedure, appropriate space must be identified to provide pre- and postprocedure care. In addition, any patient receiving anesthesia for a procedure must be monitored in an appropriate location equipped for that purpose with skilled nursing staff and the availability of an anesthesia provider during the recovery period.[12] The same safety standards implemented for procedures performed in the OR must be assured for all NORA cases regardless of where they are provided.

Supplies and Equipment

No matter what type or level of anesthetic care is anticipated to be required to facilitate completion of a procedure, for the majority of locations and clinical situations an anesthesia machine should either be present or readily available in anticipation of the need to convert to general anesthesia and/or require mechanical ventilatory support. If the proposed location for a procedure cannot accommodate anesthesia equipment (for size, electrical, or other spatial reasons), an alternative location should be identified.

All anesthetizing locations should have appropriate monitoring equipment. While the monitoring needs may vary for each procedure, the usual monitoring equipment should be available, preferably the same equipment that is available in the ORs to ensure that all providers know how to use and troubleshoot the equipment. The ASA Standards for Basic Anesthesia Monitoring[13] may serve as a fundamental guide, but often specific procedures require more than basic monitoring. As sicker patients are increasingly cared for in NORA locations, monitoring needs must be considered to ensure that the patient receives appropriate care to address both procedural needs and any clinical issues that may arise as a result of underlying medical conditions. The appropriate monitors increase the likelihood of early detection and amelioration of problems and undesirable outcomes. The success in establishing and maintaining unparalleled safety records in the OR results largely from the consistent use of appropriate monitoring equipment. The same standards should apply in NORA settings.

MONITORING IN NON-OPERATING ROOM ANESTHESIA LOCATIONS

Physiologic monitoring is a critical feature of safe anesthesiology practice wherever the anesthetic is delivered (see also Chapters 36 and 41). Just as monitoring standards of care exist throughout the OR, they must be consistently in place in NORA locations as well. Some studies suggest that adverse events occurring outside of the OR may in fact be associated with more deleterious outcomes and serious injury than those in the OR because minimal monitoring standards are lacking.[14,15] Monitoring in NORA locations is often suboptimal because the need is not identified by anesthesiologists and, in some cases, the proceduralist is not well-educated about what may be required. Until recently, pulse oximetry was the primary monitoring used to assess adequacy of oxygenation *and* ventilation, despite the fact that pulse oximetry has significant limitations. Several publications indicate significant misunderstanding among non-anesthesiologists using pulse oximetry to monitor patients outside of the OR.[16] Anesthesiologists providing services outside of the OR should clarify the need for both pulse oximetry and monitors of ventilation. Several excellent articles and websites are available as resources.[17] Over the last 20 years, capnography has become the standard of care for monitoring not only for ventilation, but also for circulation and metabolism[18-20] by directly measuring expired carbon dioxide levels and indirectly measuring production of CO_2 at the tissue level and delivery of CO_2 to the lungs. Despite broad utility and clear clinical superiority, capnography is not always available in non-OR locations. The mandate for capnography may not be understood by either proceduralists or hospital administrative staff without significant education about its utility. Capnography equipment is bundled with other monitoring equipment on the anesthesia machine. Similar monitoring should be routinely available in NORA locations independent of the anesthesia machine which may not be required for every case.

PREPROCEDURAL EVALUATION FOR NON-OPERATING ROOM ANESTHESIA CASES

Preprocedural evaluation is an essential component of anesthesia practice, regardless of where the procedure is performed or who is performing it (see also Chapter 31). Increasingly, patients with serious comorbidities and/or significant compromise are scheduled to undergo procedures outside the OR. For many of these patients, preprocedure assessment identifies clinical issues that may be difficult to optimize prior to proceeding with the procedure. In some cases the procedure is an emergency or of such urgency that a delay to address underlying clinical issues is not possible. For all NORA cases, the ASA Guidelines for Preanesthesia Evaluation[21] of 2012, should guide management. They specifically define a preanesthesia evaluation which should, at a minimum, include the following:

1. A patient interview that includes a physical examination and a review of medical, surgical, anesthetic, and medication history
2. Diagnostic laboratory tests and other relevant diagnostic information
3. Assessment of ASA status
4. Formulation of potential anesthetic plans and presentation of these to the patient

Because several studies have dispelled the notion that there is a body of routine testing that reduces anesthetic risk,[22,23] anesthesiologists should obtain testing based on the patient's history, the procedure they are to undergo, and anesthesia requirements. Since many NORA cases are performed as urgent referrals to a proceduralist, patients may not have been evaluated by any provider prior to the procedure. As a result, accumulating the appropriate clinical information in a timely manner may be challenging, if possible at all. For patients known to have significant underlying medical conditions, the proceduralist should require that, if possible, the patient be evaluated in a preoperative evaluation clinic (if one is available). If not, the patient may require an extensive preprocedure assessment that could delay the procedure or necessitate rescheduling at a later time. Occasionally, periprocedural admission or consultation with a specialty service is required. Guidelines regarding preanesthetic evaluation can be found in Chapter 31 and many other texts[24]; in general, the same guidelines apply to procedures performed in the OR or non-OR locations.

OTHER CONSIDERATIONS

Additional issues must be considered for patients undergoing NORA procedures, particularly related to the management of underlying clinical conditions or periprocedure needs that might not be anticipated by other providers. These include the following limitations that should be considered before proceeding:

1. Many procedure suites have beds with lower weight limits and less mobility than OR beds.
2. Procedure suites for fluoroscopy have beds that cannot be placed in Trendelenburg or reverse Trendelenburg position.
3. Anticoagulation status is often an issue and guidelines may be extended for some procedures.
4. Renal status may impact the use of contrast.
5. During percutaneous procedures, bleeding may be occult, and the potential need for transfusion should be addressed preprocedurally.
6. Percutaneous procedures often require that the patient remain still. Patients with extreme anxiety, chronic pain, claustrophobia, mental disability, movement disorders, obesity, or obstructive sleep apnea (OSA) or those who are at the extremes of age may not tolerate lying on a table for long, even if the proposed procedure is not very stimulating. For these patients, deeper sedation or general anesthesia may be needed.

Current NPO guidelines for procedures are 6 hours for a light meal, 8 hours for a full meal, and 2 hours for clear liquids applied to patients without increased risk for aspiration (gastroesophageal reflux disease, gastric dysmotility, hiatal hernia, diabetes mellitus, bowel obstruction, or intraabdominal pathologic conditions).[25] This is often a source of disagreement between anesthesiologists and proceduralists, who may not realize the ramifications of a full stomach or may insist that contrast or barium be administered before the procedure. Timely preprocedure evaluation and enforcement of clear standards for NPO status can help prevent scheduling mishaps and unnecessary delays and cancelations. This may require education of the proceduralists and their staff.

Specific Procedure-Related Issues

GASTROINTESTINAL PROCEDURES IN THE ENDOSCOPY SUITE

Over the past 10 years, enormous growth in the number of gastrointestinal (GI) endoscopic procedures related to an aging patient population, increased awareness of cancer screening benefits, broad-based reimbursement for screening colonoscopies, and better technology is quite evident.[26] Increasingly complex procedures, higher-acuity patients, and increased case volume broaden the scope of challenges anesthesiologists face in caring for these patients. The choice of anesthetic approach requires a thorough understanding of both the procedure and the comorbidities of the patient. Similarly, preprocedure evaluation and postprocedure care, which carry financial and operational constraints, assume greater importance. Historically, most endoscopists managed healthy patients undergoing minor procedures with moderate sedation administered by nurses. However, moderate sedation is often inadequate in the context of sicker patients for simple procedures or healthy patients for complex procedures. Therefore, this chapter discusses the focus and methods of common GI procedures, reimbursement issues that may affect practice, the frequent comorbidities associated with patients undergoing those procedures, and anesthetic approaches suggested by anesthesiologists with expertise in the area.

A broad spectrum of GI procedures takes place in the endoscopy suite, ranging from routine screening colonoscopies to complex endoscopic pancreatic necrosectomies. Each of these requires specific levels of anesthesia depending on the invasiveness and stimulation imposed by the procedure as well as patient factors relating to their comorbidities. The most common procedures are esophagogastroduodenoscopy (EGD), sigmoidoscopy and colonoscopy, and endoscopic retrograde cholangiopancreatography (ERCP).

Reimbursement Constraints

Rapid increases in charges to Medicare and private insurance companies for anesthesiology support of colonoscopies provoked the attention of both Medicare and commercial payers. As a result, in 2008, a major insurance company amended its reimbursement policies[27] stating that they would no longer pay for anesthesiologists to administer propofol for screening colonoscopies in routine cases and that costs would be reimbursed only if the patients had documented comorbidities that would likely contraindicate moderate sedation. The carrier's actions were prompted by an acute rise in billing, significant regional differences in the use of propofol for routine colonoscopies, and the growth of independent colonoscopy centers that treated many patients per day facilitated by the use of propofol, which permitted very rapid turnover of cases. Despite the fact that the list of acceptable comorbidities included more than 200 diagnoses, nationwide protests from patients and physicians prompted the carrier to delay and then cancel implementation of this policy change. The finances of this situation continue to drive practice, and the debate continues. Anesthesiologists must continue to consider patient need and procedural requirements as the criteria by which anesthetic plans are formulated because the political and economic aspects of the debate will undoubtedly continue.

Esophagogastroduodenoscopy

EGD involves examination of the upper GI tract (esophagus, pylorus, and stomach) using a fiberoptic endoscope. The most difficult parts of the procedure for the patient include passing the scope into the esophagus (past the cricopharyngeus muscle) and through the pylorus. Any interventions that occur during the procedure (biopsy, resection, dilation) should be discussed with the endoscopist before the procedure because they constitute additional procedure time. Important and potentially stimulating therapeutic undertakings during endoscopy include hemostasis, biopsy, stenting, dilation, and mucosal or submucosal dissection.[28]

Most patients tolerate this procedure well with opioid or benzodiazepine sedation, but for those who are hemodynamically unstable, at risk for obstruction or aspiration, very anxious patients, or for children, general anesthesia may be the best alternative. Unfortunately, many patients presenting for EGD are in this high-risk category, including patients with severe GI reflux disease, morbid obesity, asthma, or OSA. In some cases, thorough topicalization is all that is needed, but in some patients, this is inadequate for the procedure or is difficult to achieve. ProSeal laryngeal mask airways (LMA), which have a built-in gastric drainage port, permit the passage of a pediatric endoscope, and this approach may be the best option for children and other patients[29] who require general anesthesia and are appropriate for LMA use. As with all procedures above the nipple line that use cautery, precautions must be taken to reduce the potential for airway fires.[30] This subject is discussed in Chapter 44. Rare, but serious complications include aspiration and gastroesophageal injury including perforation.

Sigmoidoscopy and Colonoscopy

Sigmoidoscopy and colonoscopy can be diagnostic and/or therapeutic and involve the examination of the lower GI tract, including either the sigmoid colon only or up to the distal ileum. This examination can be difficult for some, although most patients tolerate it with a combination of benzodiazepines and opioids. Interventions such as biopsies or polyp removal may require increased analgesia. Most anesthesiologists provide sedation with propofol; however, even in situations in which GI endoscopists are permitted to direct nurses to administer propofol, one study found that the mean bispectral index (BIS) score of patients was 59, indicating they were under general anesthesia.[31] Some gastroenterologists maintain that this depth of sedation or anesthesia allows for more thorough examination, but no data have indicated that a better examination is performed. Remifentanil has been compared with propofol in the context of sedation for colonoscopy. Although patients given remifentanil recovered earlier, they also had more nausea and respiratory depression than the propofol groups. When inhaled anesthetics such as sevoflurane and nitrous oxide were compared with total intravenous anesthesia (TIVA) using drugs such as propofol, fentanyl, and midazolam in patients undergoing colonoscopy, the TIVA group emerged faster but had longer-lasting psychomotor impairment than the inhalational group.[32-34]

As with upper endoscopy, specific interventions during sigmoidoscopy and colonoscopy constitute additional stimulation including introduction of the endoscope, colonic insufflation, advancement of the endoscope, and additional endoscopic intervention such as biopsy, polypectomy, stenting dilation, and mucosal resection.

The ability and need to titrate a drug quickly and appropriately drive the choice of anesthetic, and new studies looking at patient-controlled sedation pumps are under way. Studies of patient satisfaction and indicators of procedural success are ongoing, as are several trials of patient-administered sedation and other types of computerized pumps.

One potential complication is bowel perforation, which is heralded by ongoing abdominal pain; emergent surgical intervention is indicated in this situation. Bleeding is another complication that can occur during therapeutic lower GI procedures. A current blood bank sample is imperative as well as adequate intravenous access.

Endoscopic Retrograde Cholangiopancreatography

ERCP is a fluoroscopic examination of the biliary or pancreatic ducts accomplished through an endoscopically guided injection of contrast through the duodenal papilla. This type of procedure constitutes the up-and-coming interventional gastroenterology field. Patients are usually in the prone position. Many patients who require ERCP are compromised. Their diagnoses include cholangitis (with or without sepsis), pancreatitis, bile duct obstruction secondary to stones, or pancreatic or hepatocellular tumor masses. Potentially stimulating interventional maneuvers during ERCP include sphincterotomy, hemostasis, stent placement, stone extraction, pancreaticobiliary visualization, and laser lithotripsy.

These procedures can range from straightforward to highly complex interventions. Furthermore, gastric insufflation is required and most proceduralists prefer CO_2 instead of air. Consequently, prolonged procedures can lead to very high arterial CO_2 levels. Procedural failure rates are twice as high for sedation patients as they are for general anesthesia patients, and the complication rate for general anesthesia cases may be lower.[35,36] In addition, the patient's airway is effectively inaccessible to the anesthesiologist and ventilation can be challenging. For this reason, many anesthesiologists prefer general anesthesia for ERCP.

NATURAL ORIFICE TRANSLUMINAL ENDOSCOPIC SURGERY: THE NEXT FRONTIER?

Natural orifice transluminal endoscopic surgery (NOTES) represents an approach to abdominal and peritoneal procedures that integrates the perspectives of endoscopic medicine and minimally invasive surgery. The use of NOTES in humans is in the early phases, and several cases have been reported of transvaginal and transgastric cholecystectomy.[37,38] Thus far these cases have required a pneumoperitoneum and general anesthesia; however, as technology improves, these parameters may change and NOTES procedures may take their place among the numerous other interventions performed outside the OR.

An example of a NOTES used by GI endoscopists to treat esophageal achalasia is peroral endoscopic myotomy (POEM). Esophageal achalasia is characterized by poor peristalsis of the esophagus in combination with increased muscle tone and incomplete relaxation of the lower esophageal sphincter (LES). Symptoms arising from impaired entry to the stomach include nausea and vomiting, dysphagia, and/or pain. The POEM procedure has been developed as a minimally invasive procedure to correct achalasia by endoscopically insufflating the esophagus with CO_2 and then making an incision into the mucosa from the mid-esophagus (through the gastroesophageal [GE] junction) to 2 to 3 cm into the proximal stomach. During insufflation, patients may have an increase in $ETCO_2$ that can be controlled using mechanical ventilation. Potential risks of insufflation range from subcutaneous emphysema to pneumothorax, pneumomediastinum, and pneumoperitoneum. This procedure commonly requires several hours and is best accomplished using general anesthesia with an endotracheal tube, which protects the patient from aspiration of gastric contents and allows the anesthesiologist to minimize the perils of CO_2 insufflation. As with all NORA procedures, vigilance, teamwork, and communication are vital to ensure not only the success of the procedure but the safety of the patient as well.

Interventional Pulmonary Procedures

Innovations in interventional pulmonology have expanded the pulmonary field tremendously. Bronchoscopic interventions have grown to encompass many traditional surgical procedures performed in the OR. Anesthesiology services are required for high-risk patients and given the nature of the procedures involving the airway, the potential for complications is high. Fluoroscopy plays a major role for these procedures. Discussion, communication, planning, and radiation safety are particularly critical in this environment.

COMMON BRONCHOSCOPIC PROCEDURES

Common bronchoscopic procedures include the following (see also Chapter 53):

1. Endobronchial stenting: placement of self-expanding metallic stents to treat stenosis
2. Endobronchial biopsy, laser treatment, and cauterization
3. Balloon dilation and cryotherapy

Technological advances in this field have given rise to new innovative procedures used in treating a broader patient population. Several interventions that represent amalgamations of preexisting technologies in the bronchoscopy suite are as follows:

1. Endobronchial ultrasound-guided transbronchial needle aspiration (EBUS-TBNA). This procedure is used to image the bronchial wall and adjacent structures. It allows ultrasonic visualization of mediastinal lymph nodes and other peribronchial lesions and therefore is a useful staging tool.
2. Electromagnetic navigation bronchoscopy (ENB). This technique permits biopsy of endobronchial tissue that is not visible using computer software that creates a virtual multiplanar lung reconstruction from computed tomography (CT) data. A sensor probe and electromagnetic location board guides the operator to the appropriate location during the bronchoscopy.
3. Fiducial marker implant. Markers are placed before stereotactic radiosurgery via bronchoscopy or ENB.[39]

Novel Anesthetic Concerns

The site of intervention creates several special anesthetic considerations. Preoperatively it is important to review common comorbidities, which in these patients include obstructive and restrictive lung disease, cardiac disease, malnutrition, chronic aspiration, and tobacco and alcohol use. Although simpler procedures may be completed with sedation, complex procedures may require general anesthesia. Because a rigid bronchoscope is used during some aspects of these interventions, intravenous anesthetics are preferred. Instrumentation of the airway and insertion of biopsy or therapeutic equipment will compromise delivery of inhaled anesthetics to the patient and potentially pollute the procedure room. Propofol and remifentanil infusions are well tolerated and can be titrated to effect. Dexmedetomidine may be used as well. Processed EEG monitoring may be helpful, though no data document the specific value of this type of monitoring for these procedures. Use of muscle relaxants is also preferred to prevent coughing and eliminate any chest wall rigidity. Muscle relaxation also facilitates introduction of bronchoscope. The use of steroids during and after treatment has not been demonstrated to be effective in reducing edema. For patients whose airway is not controlled during the procedure, aspiration is a potential risk. For this group of patients, administration of antiemetics and dexamethasone may be helpful.[40] High-frequency jet ventilation (HFJV) has been increasingly used to provide ventilation and as a strategy to provide a static field during therapeutic pulmonary interventions. Complications commonly encountered include airway obstruction, bronchospasm, bleeding, hypoxia, and airway fire (see also Chapter 70). Because potential complications are significant, patients should be observed in an appropriate unit postprocedure and, if needed, admitted to the hospital for overnight observation.

Anesthesiology for Image-Guided Interventions: Evolution of a New Interface

In the 1950s the field of radiology was redefined by Charles Dotter, the father of IR.[41] Through his pioneer work with the treatment of peripheral atherosclerotic lesions and angioplasty, the specialty grew from being diagnostic to one that now encompasses an ever-expanding menu of interventional undertakings, in keeping with technology development and patient needs. The scope of procedures performed in IR settings is as broad as the number of diagnoses known to the medical profession and is expanding. In fact, not all interventional radiation procedures are performed by radiologists. Some take place in specialty areas with other names, such as catheterization laboratories, neuroradiology suites, CT scanners, magnetic resonance imaging (MRI), and even in ORs. Some are performed by interventional cardiologists or surgeons. For that reason the discussion will address the purpose for which they are performed rather than categorizing them by the location in which they are performed or the specialty of the person performing the procedure. The common characteristics shared by most of these interventions are that there are no surgical incisions, there is some type of imaging involved (fluoroscopy, ultrasound, CT, positron emission tomography [PET], MRI), and access to the organ, tumor, or vascular structure in question is through a small hole by wires or catheters. Beyond that, the array of available technologies and possible interventions (both diagnostic and therapeutic) is astonishingly broad. The scope and intensity of procedures undertaken in interventional suites rivals that of surgeries performed in any OR, and often, patients undergoing non-OR procedures are sicker than those undergoing conventional surgeries. Unfortunately, they often lack preoperative evaluation and are not medically optimized. Frequently non-OR patients become candidates for noninvasive procedures precipitously because they are felt to be too sick or too high risk for the OR or because the need for intervention develops urgently or emergently.

It is important that anesthesiologists make the effort to understand the planned course of the procedure and the nature and acuity of the patient's comorbidities, which may not be apparent to the proceduralist. As in the OR, the challenge is to think preemptively about how the prospective procedure will affect the patient's physiologic status and design a successful anesthetic plan for the case. However, the additional caveat, as with all non-OR anesthetics, is that this may require learning about a procedure, technology, or modality that may be novel, unfamiliar, or in clinical trial. Also, it may fall to the anesthesiologist to introduce the potential ramifications of the patient's comorbidities and anesthetic risks to the proceduralist in a constructive manner. Many interventional specialists are consultants and are not involved in the primary care of the patients they are treating. They may be unaware of seemingly peripheral aspects of their patient's physical status that are in fact quite central to positive outcome. Creating a clear, collegial, and workable path of communication between medical proceduralist and anesthesia provider is paramount. The need for anesthesia support may reflect the needs of the patient and not the complexity of the procedure. The interventionalist may be highly focused and technically oriented and may not understand the concerns of an anesthesiologist. Our mutual tasks are to understand what needs to be accomplished and to bring our skills to bear in a manner that bridges the knowledge gap, creating an atmosphere of safe and reliable interdisciplinary collaboration that optimizes outcome.

Diagnostic and Therapeutic Interventions: New Challenges

The need for anesthesia during minimally invasive procedures continues to grow as the scope of image-guided interventions broadens. In addition, as the population ages and technologic advancement marches forward, image-guided procedures will continue to supplement and perhaps replace conventional surgeries, especially for patients whose comorbidities make traditional surgical approaches risky. Image-guided procedures, although noninvasive, can cause anxiety and postprocedural pain and carry the risk for potentially life-threatening complications. Anesthesiologists are called on to keep patients safe and comfortable and to facilitate optimal outcomes. Image-guided interventions may be diagnostic, therapeutic, or both. Many diagnostic procedures are short and tolerated well with nothing more than conscious sedation; however, for a compromised patient, even the most minor procedure can be problematic. Interventional procedure suites impose constraints not normally encountered in the OR. Additional considerations that emerge in these environments include unfavorable equipment layout, radiation exposure, occult bleeding risk, and contrast allergies.

These procedures have some special issues that need to be addressed by the anesthesia providers to optimize patient care and protect themselves.

EQUIPMENT LAYOUT

The layout in any radiology suite can be problematic for anesthesiologists because x-ray tubes and moving C-arms create a zone of inaccessibility around the patient's head and limit placement of the anesthesia machine. This necessitates the use of extensions on ventilator circuits and intravenous lines, increasing the potential for mishap. Infusion pumps, blood warmers, and other monitors must be placed far away from moving imaging equipment to prevent them from being knocked down or tangled during C-arm rotation and movement. In addition, imaging screens are often at right angles to the anesthesiologist, making it impossible to see what the interventionalist is doing or assess the progress of the case. Anticipating events is therefore difficult unless good communication occurs between the anesthesiology and radiology teams.

Radiation Exposure

Radiation exposure is a serious consideration for anesthesiologists, and steps must be taken to minimize it. Most exposure results from scatter of the x-ray beam. The specifics are not discussed in this chapter; however, excellent discussions and guidelines for optimization of radiation safety are readily available (see also Chapter 89).

Many anesthesiologists do not undergo consistent or repetitive training in radiation safety. All radiation exposure should follow the ALARA ("As Low As Reasonably Achievable") principle. The radiation beam attenuates based on the inverse square of the distance from the radiation source ($1/d^2$).[42] Shortened exposure time, increased distance from the source of radiation, and barriers to radiation (lead shielding and screens) are three ways in which to reduce exposure. It is important that anesthesia providers wear properly fitting lead shielding; ill-fitting lead shielding is suboptimal as lead shielding is maximally protective only if it fits properly. Protective equipment should include the use of thyroid shields and leaded glasses. Anesthesiologists should routinely use portable lead screens and wear radiation badges that are monitored on a monthly basis. Even so, several recent studies indicate that exposure of anesthesia personnel to radiation is quite high and that the exposure of the head and face of anesthesiologists can exceed three times the exposure of radiologists[43] because of their position in the room.

Related to the exposure problem is the need for the anesthesiologist to leave the room during specific imaging runs such a digital subtraction angiography (DSA), a novel aspect of NORA. This can be planned and executed so that it does not interfere with the anesthetic or compromise safety.

Contrast Material

Contrast material is commonly administered during interventions guided by imaging. Standard ionic, high-osmolality contrast agents are associated with dose- and concentration-dependent adverse reactions in 5% to 8% of patients. Idiosyncratic reactions are unrelated to dose or concentrations administered.[44] Reactions can be severe and include laryngeal edema, bronchospasm, pulmonary edema, hypotension, and respiratory arrest or seizures. Oxygen, epinephrine, and bronchodilators are the recommended rescue regimen. For pretreatment of patients with a history of contrast reaction, steroids and diphenhydramine are recommended. Numerous prophylactic protocols exist, but none have shown superiority.[45] The use of low-osmolality contrast reduces the risk for adverse reactions but does not eliminate the risk. Patients with renal insufficiency are at risk for contrast-induced nephropathy (CIN). Risk is further increased for patients with diabetes mellitus. Despite mixed evidence, these patients should undergo prophylactic protection strategies including a combination of periprocedural hydration.[46-48] Carbon dioxide can be used as an alternative if contrast is absolutely contraindicated. Contraindications to carbon dioxide include patients with patent foramen ovales (PFOs) or any right-to-left shunting.[49]

Bleeding

During most percutaneous interventions bleeding may be occult while in some it is the reason for the procedure (i.e., splenic embolization). This is a serious concern, especially for patients receiving anticoagulation (see also Chapter 50). Guidelines for optimizing coagulation parameters change frequently and are procedure dependent. For patients who do not undergo anticoagulation for other reasons, the international normalized ratio (INR) should be less than 1.5 and the platelet count more than 50,000. If possible, warfarin should be held for 5 to 7 days before the procedure, clopidogrel and aspirin for 5 days, and fractionated heparin for 12 to 24 hours. Heparin infusion should be stopped 4 to 6 hours before the procedure. Nonsteroidal antiinflammatory drugs (NSAIDs) should be held for 1 to 2 days, if possible.[50] As mentioned earlier, certain percutaneous procedures may proceed with anticoagulation on board (i.e., cerebral angiogram). It is not unreasonable to send a sample to the blood bank for any patient undergoing high-risk interventional procedures (e.g., transjugular intrahepatic portosystemic shunts [TIPs]). Of course, it is critical to communicate clearly with the interventionalist prior to the planned intervention or when hemodynamic parameters change or the initiation of blood pressure support becomes necessary. Often the therapeutic modality can be used for diagnostic purposes.

VASCULAR INTERVENTIONAL PROCEDURES

Angiography, the general term for imaging of blood vessels, includes arteriography and venography (see also Chapter 56). This involves the acquisition of images during injection of contrast material. In many institutions, this technique has been replaced by CT angiography (CTA). DSA, a technique that imposes a contrast-injected image on top of a previously acquired non-contrast image, improves accuracy. Arteriography can be used to evaluate atherosclerotic and ischemic disease, define the arterial supply of tumors and vascular anomalies, and define traumatic injury. After diagnostic imaging, interventions using balloons, stents, balloon-mounted stents, or delivery catheters take place. Follow-up arteriography is used to evaluate the result. In some cases, arteriography serves as a precursor to later surgery.

Thrombolytic therapy can be delivered to veins, arteries, or conduits that are thrombosed. The earlier the intervention the more successful it is likely to be. Various agents are used, including recombinant tissue plasminogen activator (r-TPA), urokinase, and others.[50-52] Thrombolytic therapy is generally contraindicated in patients with ongoing bleeding, recent bleeding, pregnancy, known allergy to thrombolytic agents, suspected aortic dissection, or the presence of a nonviable extremity.

Embolization therapy is used in a wide range of conditions, including trauma, hemorrhage, vascular anomalies, fibroids, aneurysms, and tumors. The goal is to occlude arteries or veins either temporarily or permanently. This can be done mechanically with coils, balloons, or glue or with chemical agents that are temporary (Gelfoam) or permanent (alcohol). In these cases, arteriography first defines and localizes the lesion and the embolic agent is then delivered to the appropriate place with imaging guidance.

For all of these vascular interventions, the nature of the case, the comorbidities of the patient, and the intricacies of the procedure will determine the need for and extent of an anesthesiologist's involvement. Complications to anticipate include bleeding during thrombolysis, undesired embolization of nearby structures during embolization, and vessel disruption. Depending on where the target vessels are, potential complications should be appropriately anticipated in terms of planning for physiologic sequelae and the need for blood products.

Venography or imaging of the venous system is used in the context of stent placements, inferior vena cava (IVC) filter placement or removal, pulmonary arteriography, embolization of pulmonary arteriovenous malformations (AVMs), thrombolysis, and selective venous sampling. Central venous angioplasty is most frequently undertaken in patients who have indwelling devices. IVC filters are placed to minimize the risk for pulmonary embolus arising from the migration of deep vein thromboses from the lower extremities or pelvic veins. Indications for IVC placement include high risk for pulmonary embolism, failure of anticoagulation or contraindications for anticoagulation, and allergy to anticoagulants. Both removable and permanent filters are available and can be placed via transfemoral or transjugular approach. For the most part, these procedures require little or no sedation; however, patients who cannot lie flat or with extreme anxiety will need anesthesia support. Pulmonary arteriography is used less frequently than in the past because of the speed and reliability of pulmonary CTA; however, the procedure is useful to evaluate pulmonary hypertension.[52] This modality is also useful for diagnosis and treatment of pulmonary and bronchial AVMS and pseudoaneurysms.

Fistulograms, graftograms, and tunneled hemodialysis (HD) lines, grouped collectively as hemodialysis vascular access procedures, represent a unique type of vascular interventional case and a large percentage of IR caseload. Their uniqueness derives from the fact that the patient population is entirely comprised of those with end-stage renal disease (ESRD). These patients often require multiple interventions in the maintenance of their dialysis access lines. Vascular access dysfunction may be due to failure of maturation of an arteriovenous (AV) fistula, excessive bleeding or increased pressures during dialysis, or clotted vascular access. As a result, these patients require both diagnostic procedures such as fistulograms and therapeutic interventions such as balloon angioplasty and thrombectomy.[53] Anesthesia care is needed as ESRD is rarely an isolated medical condition and this patient population tends to have multiple complex medical comorbidities that are often not optimized. Patient evaluation is like any procedure requiring anesthesia care with special consideration placed on volume status, serum potassium level, and electrocardiograph (ECG) changes. Patients with dysfunctional access require special attention to these parameters, as dialysis runs are often suboptimal. Care must be taken to weigh the risks and benefits of proceeding with borderline high potassium levels versus postponing the case and asking for a temporary dialysis line to get potassium to reasonable levels. Sedation is adequate in most cases. However, angioplasty can cause extreme discomfort for some patients, especially in cases where access is distally located (radiocephalic fistulas). Regional anesthesia techniques can be tailored for these cases but care must be taken as these patients are often on chronic anticoagulation. For patients unable to lie flat, ramping can be useful. Most patients have a history of prior anesthetics and this can guide future anesthetic plans. Procedure duration can range from very short (<30 minutes) to very long (several hours or more) depending on whether there are multiple stenotic areas or whether thrombectomy needs to be performed. Thrombectomies present a special consideration as declotting procedures use r-tPA. Thrombus can be dislodged from the fistula/graft and travel into the circulation. Patients with severe pulmonary hypertension or right ventricle failure should be considered for open surgical thrombectomy.[54]

BILIARY AND HEPATIC INTERVENTIONS

Procedures to treat biliary or hepatic pathology are particularly challenging in that they are painful, intricate, and technically demanding. Patients are often extremely compromised. Hepatic and biliary procedures include transhepatic cholangiography, percutaneous transhepatic biliary drainage, hepatic venography with hemodynamic measurement, liver biopsy and the creation of TIPS, and portal vein embolization (PVE). Patients scheduled for biliary procedures may present with jaundice, cholangitis, shock, bile duct leak, or other related abnormalities. Clearly, significant comorbidities accompany these disorders. Contraindications for these procedures include bleeding diathesis, inability to tolerate contrast, and the presence of large hepatic AVMs, significant ascites, and hydatid disease.

Biliary drainage is accomplished by placing the patient supine on the table and inserting a long needle obliquely into the hepatic parenchyma (the ninth intercostal space). Contrast is delivered with the goal of imaging the necessary structures. Cholecystostomy tube placement is performed to improve symptoms in patients with acute cholecystitis but who are not candidates for surgery. Here, the gallbladder is imaged with ultrasound, CT, or fluoroscopy; the gallbladder is accessed through a needle that traverses the liver; and a drainage catheter is placed. For these procedures, the choice of anesthetic depends entirely on the patient's body habitus, comorbidities, and pain tolerance. Obese patients are difficult to image, and optimization of needle position also can be difficult. Patients may present with a history of tolerance to opioids and with compromised metabolism, which requires careful choice of drugs. Regional anesthesia may be useful for procedural or postprocedural pain management.[55] Lying flat may be difficult for patients with pulmonary compromise or ascites.

Hepatic venography and hemodynamic assessment are performed to assess suspected venous anomalies (Budd-Chiari) and quantitation of portal hypertension. Liver biopsies can be performed during these procedures. Access for these procedures is usually transjugular and involves needle insertion followed by wire access and insertion of a long vascular sheath. Many patients find this extremely difficult to tolerate. Hepatic venography and pressure monitoring is done through an angled catheter before it is advanced to wedge in the hepatic vein. A calculation of corrected sinus pressure, the difference between free pressure and wedge pressure, defines the degree of portal hypertension.[56] The creation of a portosystemic shunt requires positioning of a needle advanced through the hepatic parenchyma and into the portal vein. The parenchymal tract is dilated with an angioplasty balloon and a stent is inserted. This is a painful and difficult procedure, vastly oversimplified for clarity. It may be quite lengthy and general anesthesia is advisable. Indications for the creation of TIPS include repeated esophageal variceal bleeding refractory to medical treatment and intractable ascites. It is often used as a bridge to liver transplant. Relative contraindications to this procedure include preexisting hepatic encephalopathy and ongoing alcohol abuse, which preclude liver transplantation. In elective situations, significant pulmonary hypertension, valvular heart disease, and congestive heart failure are contraindications to this procedure.[57] TIPS can be performed emergently in patients with end-stage liver disease as a way to treat ongoing bleeding. The risk for bleeding from TIPS is high and a blood bank sample should always be obtained. Adequate access and blood products, including fresh frozen plasma (FFP) should be secured. PVE is a relatively new technique designed to reduce blood flow in hepatic segments containing tumor while encouraging hypertrophy of remaining hepatic tissue. The goal is to improve survival among patients undergoing resection of hepatic neoplasms by increasing postsurgical hepatic tissue mass. Embolization is accomplished with portal vein angiography and coils. Postprocedure pain can be significant. Acute complications include bleeding, bile leak, pleural insults, and contrast reactions.

GASTROINTESTINAL AND GENITOURINARY INTERVENTIONS

Interventional radiologists perform direct-access GI procedures, the most common of which is the percutaneous gastrostomy tube (G-tube). Other variants include cecostomy and jejunostomy tubes. For G-tube placement, the stomach is distended with air via a nasogastric (NG) tube or a small French catheter and glucagon administered to decrease gastric emptying. Subsequent gastropexy is performed by some practitioners as a means of stabilizing the stomach; the stomach is entered with a needle and a wire and an appropriate tube is inserted and placed in the proper location. Acute complications include bleeding, violation of adjacent structures, and peritonitis. In many cases, these procedures can be tolerated with sedation except in situations where patients are at high risk for gastric aspiration (e.g., esophagectomy).

Genitourinary (GU) procedures in the radiology suite focus on obtaining direct access to the renal collecting system. Dilation and stenting can be performed, and suprapubic cystostomy is also a procedure commonly performed in radiology suites. Nephrostomy tube placement is performed to divert urine in the face of obstruction from stones, tumor, or other obstructive pathology. In general, the technique involves injecting contrast medium, identifying the renal pelvis, accessing it, and inserting a tube.[58] Prone positioning of the patient is preferred, which generates an attendant list of potential anesthesia concerns including airway issues, pain management, access, and more. In formulating the anesthesia plan, one must carefully weigh the risks and benefits of prone sedation versus general anesthesia. Factors to take into consideration include patient body habitus and hemodynamic condition, proceduralist skill, and duration of procedure (e.g., accessing a dilated renal pelvis in a thin patient may be quicker than in a morbidly obese patient).

PERCUTANEOUS INTERVENTIONS FOR ONCOLOGY

Interventional oncology is a rapidly expanding area and is revolutionizing oncologic care. These treatment modalities are gaining momentum over surgical interventions. Imaging guidance is achieved via CT, ultrasound, or fluoroscopy. Transarterial chemoembolization and percutaneous ablations (with microwave or to a lesser extent radiofrequency, laser, cryoablation, or alcohol) can be directed at tumors and image-guided insertion of radioactive materials can be performed. Commonly, hepatic, kidney, lung, and adrenal lesions are targeted. Complications are similar to those of other percutaneous interventions. Positioning depends on the site to be accessed. Anesthesia services are frequently used as these patients are truly high risk for surgical intervention. General anesthesia works best as the interventions may be intermittently painful, control of breathing may be optimal, and patient cooperation may not be compatible with the level of sedation required.[59] Postprocedure patients can experience pain, malaise, and nausea and vomiting, as part of a postembolization syndrome or postablation syndrome. High-dose steroids can be beneficial in prophylaxis and non-opioid analgesics can be beneficial in treating symptoms.[60,61]

Procedures Guided by Computed Tomography, Positron Emission Tomography, and Magnetic Resonance Imaging

COMPUTED TOMOGRAPHY

CT is now a commonly used guidance modality for a broad array of percutaneous interventions, and CT fluoroscopy, which combines the improved imaging capacity of CT with the real-time imaging of fluoroscopy, is also widely used. CT is used to guide both diagnostic and therapeutic procedures. Diagnostic undertakings include biopsies and drainage of fluid collections; therapeutic interventions include tumor ablation and injections for pain management. Procedures occurring in the CT suite encompass the usual constraints of radiation exposure on operators and anesthesiologists; patients are at risk for bleeding and contrast reaction. In addition, some special preprocedural considerations are important. Obese patients may not fit inside the scanner, and longer needles and drains may be needed. Positioning in the scanner may be difficult, and the usual airway considerations apply, especially because it is nearly impossible for the anesthesiologist to have continuous access to the head. For the most part, biopsies performed under CT guidance can be accomplished with sedation, but when the stimulation is intense, repeated breath-holds are required, or when the procedure is complex, general anesthesia may be needed. For patients with significant comorbidities (obesity, pulmonary or cardiac compromise, chronic pain, or history of difficult intubation), securing the airway before the procedure is prudent.

Computed Tomography–Guided Biopsies

CT guidance is useful for obtaining biopsy tissue for cytologic or histologic examination. Needles range from 25 to 18 gauge, and the patient is positioned to minimize the distance from skin to lesion and to maximize the safety of the approach. Liver biopsies are usually performed with the patient supine or slightly oblique, and retroperitoneal masses may require lateral decubitus or prone positioning. For the most part, it is helpful to the interventionalist if the level of sedation remains consistent throughout the procedure, so that large shifts in target location resulting from alterations in ventilation do not occur. However, levels of stimulation during these procedures can vary tremendously, presenting considerable challenge to the anesthesiologist if general anesthesia is not planned. Postprocedure bleeding can occur for these patients, especially those with bleeding diathesis (e.g., cirrhosis); thus, obtaining a blood bank sample is reasonable. Biopsies of carcinoid or adrenal tumors can be equally problematic, whether in the radiology suite percutaneously or in the OR. In both cases, stimulation of hormone release can precipitate severe hypotension or hypertension, which can be difficult to manage. If pheochromocytoma or carcinoid are suspected, pretreatment should be considered.

Computed Tomography–Guided Therapeutic Interventions

CT-guided therapeutic interventions include catheter drainage, ablation of tumors, and injections for pain management. Anesthetic planning for these procedures requires understanding of patient comorbidities and the techniques of the interventionalists. Excellent communication between anesthesiologist and interventionalist is needed for coordination of procedure and anesthetic because unanticipated patient movement or interventional shortfall can have drastic consequences for procedural outcome.

Catheter Drainage

CT-guided abscess drainage has become common. Options include the modified Seldinger and trocar techniques. Although local anesthesia may suffice for superficial collections, the insertion or dilation phase of the needle or trocar and the subsequent anticipated trajectory required for deeper fluid collections may be quite painful. Before the procedure, the proceduralist and anesthesiologist should discuss the intended approach, potential anesthetic choices, and backup planning for transitioning to a deeper plane of sedation or anesthesia. Preemptive planning can make the difference between a smooth procedure with a good outcome and a prolonged, difficult intervention. Anesthesiologists should be prepared to treat potential complications, which can occur as a result of injury of surrounding structures.

Computed Tomography–Guided Ablation
